MANUAL OF ANATOMY

PUBLISHED BY THE JOINT COMMITTEE OF HENRY FROWDE AND HODDER & STOUGHTON
AT THE OXFORD PRESS WAREHOUSE, 17 WARWICK SQUARE, LONDON, E.C.4

CUNNINGHAM'S MANUAL

OF

PRACTICAL ANATOMY

REVISED AND EDITED BY

ARTHUR ROBINSON

PROFESSOR OF ANATOMY IN THE UNIVERSITY OF EDINBURGH

SEVENTH EDITION

VOLUME THIRD

HEAD AND NECK

WITH 233 ILLUSTRATIONS, MANY OF WHICH ARE COLOURED

NEW YORK

WILLIAM WOOD AND COMPANY

EDINBURGH, GLASGOW, AND LONDON

HENRY FROWDE AND HODDER & STOUGHTON

1921

Printed in Great Britain by R. & R. Clark, Limited, *Edinburgh.*

1st Edition, 1896.
2nd Edition, 1903.
3rd Edition, 1906.
4th Edition, 1907.
5th Edition, 1912.
6th Edition, 1914.
6th Edition, 2nd Impression, 1917.
6th Edition, 3rd Impression, 1918.
7th Edition, 1920.
7th Edition, 2nd Impression, 1921.

PREFACE TO THE SEVENTH EDITION

In this edition the general text has been revised, many new figures, representing dissections, sections and radiographs, have been introduced. The instructions for dissection have been printed in a distinctive indented type; in many cases they have been rewritten and in some cases amplified.

The latter changes, together with the additional figures, have caused so much increase of size that it has been deemed advisable to publish the book in three volumes. Vol. I.: Superior Extremity and Inferior Extremity; Vol. II.: Thorax and Abdomen; Vol. III.: Head and Neck.

As was the case in previous editions, I am indebted to Dr. E. B. Jamieson for many suggestions, for his invaluable help in the revision of the text and for the preparation of the Index.

My thanks are due to Dr. Robert Knox, to Major A. W. Pirie and to Major T. Rankin for the use of radiographs, which they very kindly prepared for me, and to Mr. J. T. Murray for the new drawings of sections and dissections.

ARTHUR ROBINSON.

Oct. 11, 1919.

CONTENTS

HEAD AND NECK.

	PAGE
Face and Frontal Region of Head,	2
Side of the Neck,	31
Posterior Triangle,	32
The Scalp and the Superficial Structures of the Temporal Region,	42
The Dissection of the Back,	55
Removal of the Brain,	98
The Anterior Part of the Neck,	120
Parotid Region,	161
Temporal and Infratemporal Regions,	167
Submaxillary Region,	183
Otic Ganglion and Tensor Veli Palatini,	199
The Great Vessels and Nerves of the Neck,	200
Thyreoid Gland—Trachea—Œsophagus,	227
Scalene Muscles and Rectus Lateralis,	231
The Lateral Part of the Middle Cranial Fossa,	234
The Orbit,	242
Prevertebral Region,	262
The Joints of the Neck,	269
Mouth and Pharynx,	277
Carotid Canal,	299
Nervus Maxillaris,	300
Nasal Cavities,	304
Spheno-Palatine Ganglion and Internal Maxillary Artery,	317
The Larynx,	322
The Tongue,	346

ENCEPHALON—THE BRAIN.

	PAGE
Blood Vessels of the Brain,	376
The Base of the Brain,	389
The Cerebrum,	396
Ventriculus Lateralis,	426
Septum Pellucidum — Fornix — Tela Chorioidea Ventriculi Tertii,	440
The Thalami and the Third Ventricle,	445
The Mesencephalon,	451
Basal Ganglia of the Cerebral Hemispheres,	458
The Parts of the Brain which lie in the Posterior Cranial Fossa,	474

THE AUDITORY APPARATUS.

External Ear,	506
Membrana Tympani,	509
Middle Ear, Tympanic Antrum, and Auditory Tube,	510
Ossicula Auditus,	517
Tuba Auditiva,	520
Intrapetrous Part of the Facial Nerve and the Acoustic Nerve,	523
Internal Ear,	527
Vestibulum,	527
Canales Semicirculares Ossei,	528
Cochlea,	529

BULBUS OCULI.

General Structure of the Eyeball,	533
Sclera,	534
Cornea,	535
Tunica Vasculosa Oculi,	536
Retina,	542
Corpus Vitreum,	543
Lens Crystallina,	545
Chambers of the Eyeball,	546
INDEX	547

A GLOSSARY

OF THE

INTERNATIONAL (B.N.A.) ANATOMICAL TERMINOLOGY

GENERAL TERMS.

Terms indicating Situation and Direction.

Longitudinalis	Longitudinal	Referring to the long axis of the body.
Verticalis	Vertical	Referring to the position of the long axis of the body in the erect posture.
Anterior Posterior	Anterior Posterior	Referring to the front and back of the body or of the limbs.
Ventral Dorsal	Ventral Dorsal	Referring to the anterior and posterior aspects, respectively, of the body, and to the flexor and extensor aspects of the limbs, respectively.
Cranial Caudal	Cranial Caudal	Referring to position nearer the head or the tail end of the long axis. Used only in reference to parts of the head, neck, or trunk.
Superior Inferior	Superior Inferior	Used in reference to the head, neck, and trunk. Equivalent to cranial and caudal respectively.
Proximalis Distalis	Proximal Distal	Used only in reference to the limbs. Proximal nearer the attached end. Distal nearer the free end.
Sagittalis	Sagittal	Used in reference to planes parallel with the sagittal suture of the skull, *i.e.* vertical antero-posterior planes.
Frontalis	Frontal	Used in reference to planes parallel with the coronal suture of the skull, *i.e.* transverse vertical planes.

Horizontalis	Horizontal	Used in reference to planes at right angles to vertical planes.
Medianus	Median	Referring to the median vertical antero-posterior plane of the body.
Medialis Lateralis	Medial Lateral	Referring to structures relatively nearer to or further away from the median plane.
Intermedius	Intermediate	Referring to structures situated between more medial and more lateral structures.
Superficialis Profundus	Superficial Deep	Referring to structures nearer to and further away from the surface.
Externus Internus	External Internal	Referring, with few exceptions, to the walls of cavities and hollow organs. *Not* to be used as synonymous with medial and lateral.
Ulnaris Radialis	Ulnar Radial	Used in reference to the medial and lateral borders of the forearm, respectively.
Tibial Fibular	Tibial Fibular	Used in reference to the medial and lateral borders of the leg, respectively.

THE BONES.

B.N.A. Terminology.	Old Terminology.
Vertebræ	**Vertebræ**
Fovea costaiis superior	Incomplete facet for head of rib, upper
Fovea costalis inferior	Incomplete facet for head of rib, lower
Fovea costalis transversalis	Facet for tubercle of the rib
Radix arcus vertebræ	Pedicle
Atlas	**Atlas**
Fovea dentis	Facet for odontoid process
Epistropheus	**Axis**
Dens	Odontoid process
Sternum	**Sternum**
Corpus sterni	Gladiolus
Processus xiphoideus	Ensiform process
Incisura jugularis	Supra-sternal notch
Planum sternale	Anterior surface
Ossa Cranii.	**Bones of Skull.**
Os frontale	**Frontal**
Spina frontalis	Nasal spine
Processus zygomaticus	External angular process
Facies cerebralis	Internal surface
Facies frontalis	Frontal surface
Pars orbitalis	Orbital plate

B.N.A. Terminology.	Old Terminology.
Os parietale	**Parietal**
Lineæ temporales	Temporal ridges
Sulcus transversus	Groove for lateral sinus
Sulcus sagittalis	Groove for sup. long. sinus
Os occipitale	**Occipital**
Canalis hypoglossi	Anterior condyloid foramen
Foramen occipitale magnum	Foramen magnum
Canalis condyloideus	Posterior condyloid foramen
Sulcus transversus	Groove for lateral sinus
Sulcus sagittalis	Groove for sup. long. sinus
Clivus	Median part of upper surface of basi-occipital
Linea nuchæ suprema	Highest curved line
Linea nuchæ superior	Superior curved line
Linea nuchæ inferior	Inferior curved line
Os sphenoidale	**Sphenoid**
Crista infratemporalis	Pterygoid ridge
Sulcus chiasmatis	Optic groove
Crista sphenoidalis	Ethmoidal crest
Spina angularis	Spinous process
Lamina medialis processus pterygoidei	Internal pterygoid plate
Lamina lateralis processus pterygoidei	External pterygoid plate
Canalis pterygoideus [Vidii]	Vidian canal
Fossa hypophyseos	Pituitary fossa
Sulcus caroticus	Cavernous groove
Conchæ sphenoidales	Sphenoidal turbinal bones
Hamulus pterygoideus	Hamular process
Canalis pharyngeus	Pterygo-palatine canal
Tuberculum sellæ	Olivary eminence
Fissura orbitalis superior	Sphenoidal fissure
Os temporale	**Temporal Bone**
Canalis facialis [Fallopii]	Aqueduct of Fallopius
Hiatus canalis facialis	Hiatus Fallopii
Vagina processus styloidei	Vaginal process of tympanic bone
Incisura mastoidea	Digastric fossa
Impressio trigemini	Impression for Gasserian ganglion
Eminentia arcuata	Eminence for sup. semicircular canal
Sulcus sigmoideus	Fossa sigmoidea
Fissura petrotympanica	Glaserian fissure
Fossa mandibularis	Glenoid cavity
Semicanalis tubæ auditivæ	Eustachian tube
Os ethmoidale	**Ethmoid**
Labyrinthus ethmoidalis	Lateral mass
Lamina papyracea	Os planum
Processus uncinatus	Unciform process

B.N.A. Terminology.	Old Terminology.
Os lacrimale	**Lachrymal Bone**
Hamulus lacrimalis	Hamular process
Crista lacrimalis posterior	Lachrymal crest
Os nasale	**Nasal Bone**
Sulcus ethmoidalis	Groove for nasal nerve
Maxilla	**Superior Maxillary Bone**
Facies anterior	Facial or external surface
Facies infra-temporalis	Zygomatic surface
Sinus maxillaris	Antrum of Highmore
Processus frontalis	Nasal process
Processus zygomaticus	Malar process
Canales alveolares	Posterior dental canals
Canalis naso-lacrimalis	Lacrimal groove
Os incisivum	Premaxilla
Foramen incisivum	Anterior palatine foramen
Os palatinum	**Palate Bone**
Pars perpendicularis	Vertical plate
Crista conchalis	Inferior turbinate crest
Crista ethmoidalis	Superior turbinate crest
Pars horizontalis	Horizontal plate
Os zygomaticum	**Malar Bone**
Processus temporalis	Zygomatic process
Processus fronto-sphenoidalis	Frontal process
Foramen zygomatico-orbitale	Tempora-malar canal
Foramen zygomatico-faciale	Malar foramen
Mandibula	**Inferior Maxillary Bone**
Spina mentalis	Genial tubercle or spine
Linea obliqua	External oblique line
Linea mylohyoidea	Internal oblique line
Incisura mandibulæ	Sigmoid notch
Foramen mandibulare	Inferior dental foramen
Canalis mandibulæ	Inferior dental canal
Protuberantia mentalis	Mental process

The Skull as a Whole.

Ossa suturarum	Wormian bones
Foveolæ granulares (Pacchioni)	Pacchionian depressions
Fossa pterygo-palatina	Spheno-maxillary fossa
Canalis pterygo-palatinus	Posterior palatine canal
Foramen lacerum	Foramen lacerum medium
Choanæ	Posterior nares
Fissura orbitalis superior	Sphenoidal fissure
Fissura orbitalis inferior	Spheno-maxillary fissure

Upper Extremity.

B.N.A. Terminology.	Old Terminology.
Clavicula	**Clavicle**
Tuberositas coracoidea	Impression for conoid ligament
Tuberositas costalis	Impression for rhomboid ligament
Scapula	**Scapula**
Incisura scapularis	Supra-scapular notch
Angulus lateralis	Anterior or lateral angle
Angulus medialis	Superior angle
Humerus	**Humerus**
Sulcus intertubercularis	Bicipital groove
Crista tuberculi majoris	External lip
Crista tuberculi minoris	Internal lip
Facies anterior medialis	Internal surface
Facies anterior lateralis	External surface
Margo medialis	Internal border
Margo lateralis	External border
Sulcus nervi radialis	Musculo-spiral groove
Capitulum	Capitellum
Epicondylus medialis	Internal condyle
Epicondylus lateralis	External condyle
Ulna	**Ulna**
Incisura semilunaris	Greater sigmoid cavity
Incisura radialis	Lesser sigmoid cavity
Crista interossea	External or interosseous border
Facies dorsalis	Posterior surface
Facies volaris	Anterior surface
Facies medialis	Internal surface
Margo dorsalis	Posterior border
Margo volaris	Anterior border
Radius	**Radius**
Tuberositas radii	Bicipital tuberosity
Incisura ulnaris	Sigmoid cavity
Crista interossea	Internal or interosseous border
Facies dorsalis	Posterior surface
Facies volaris	Anterior surface
Facies lateralis	External surface
Margo dorsalis	Posterior border
Margo volaris	Anterior border
Carpus	**Carpus**
Os naviculare	**Scaphoid**
Os lunatum	**Semilunar**
Os triquetrum	**Cuneiform**
Os multangulum majus	**Trapezium**
Os multangulum minus	**Trapezoid**
Os capitatum	**Os magnum**
Os hamatum	**Unciform**

Lower Extremity.

B.N.A. Terminology.	Old Terminology.
Os coxæ	**Innominate Bone**
Linea glutæa anterior	Middle curved line
Linea glutæa posterior	Superior curved line
Linea terminalis	Margin of inlet of true pelvis
Spina ischiadica	Spine of the ischium
Incisura ischiadica major	Great sacro-sciatic notch
Incisura ischiadica minor	Lesser sacro-sciatic notch
Tuberculum pubicum	Spine of pubis
Ramus inferior oss. pubis	Descending ramus of pubis
Ramus superior oss. pubis	Ascending ramus of pubis
Ramus superior ossis ischii	Body of ischium
Ramus inferior oss. ischii	Ramus of ischium
Pecten ossis pubis	Pubic part of ilio-pectineal line
Facies symphyseos	Symphysis pubis
Pelvis	**Pelvis**
Pelvis major	False pelvis
Pelvis minor	True pelvis
Apertura pelvis minoris superior	Pelvic inlet
Apertura pelvis minoris inferior	Pelvic outlet
Linea terminalis	Margin of inlet of true pelvis
Femur	**Femur**
Fossa trochanterica	Digital fossa
Linea intertrochanterica	Spiral line
Crista intertrochanterica	Post. intertrochanteric line
Condylus medialis	Inner condyle
Condylus lateralis	Outer condyle
Epicondylus medialis	Inner tuberosity
Epicondylus lateralis	Outer tuberosity
Tibia	**Tibia**
Condylus medialis	Internal tuberosity
Condylus lateralis	External tuberosity
Eminentia intercondyloidea	Spine
Tuberositas tibiæ	Tubercle
Malleolus medialis	Internal malleolus
Fibula	**Fibula**
Malleolus lateralis	External malleolus
Apex capituli fibulæ	Styloid process

Bones of the Foot.

Talus	**Astragalus**
Calcaneus	**Os calcis**
Tuber calcanei	Tuberosity of
Processus medialis tuberis calcanei	Inner
Processus lateralis tuberis calcanei	Outer
Os cuneiforme primum	**Inner cuneiform**
Os cuneiforme secundum	**Middle cuneiform**
Os cuneiforme tertium	**Outer cuneiform**

THE LIGAMENTS.

Ligaments of the Spine.

B. N. A. TERMINOLOGY.	OLD TERMINOLOGY.
Lig. longitudinale anterius	Anterior common ligament
Lig. longitudinale posterius	Posterior common ligament
Lig. flava	Ligamenta subflava
Membrana tectoria	Posterior occipito-axial ligament
Articulatio atlanto-epistrophica	Joint between the atlas and the axis
Lig. alaria	Odontoid or check ligaments
Lig. apicis dentis	Suspensory ligament

The Ribs.

Lig. capituli costæ radiatum	Anterior costo-vertebral or stellate ligament
Lig. sterno-costale interarticulare	Interarticular chondro-sternal ligament
Lig. sterno-costalia radiata	Anterior and posterior chondro-sternal ligament
Lig. costoxiphoidea	Chondro-xiphoid ligaments

The Jaw.

Lig. temporo-mandibulare	External lateral ligament of the jaw
Lig. spheno-mandibulare	Internal lateral ligament of the jaw
Lig. stylo-mandibulare	Stylo-maxillary ligament

Upper Extremity.

Lig. costo-claviculare	Rhomboid ligament
Labrum glenoidale	Glenoid ligament
Articulatio radio-ulnaris proximalis	Superior radio-ulnar joint
Lig. collaterale ulnare	Internal lateral ligament of elbow joint
Lig. collaterale radiale	External lateral ligament
Lig. annulare radii	Orbicular ligament
Chorda obliqua	Oblique ligament of ulna
Articulatio radio-ulnaris distalis	Inferior radio-ulnar joint
Discus articularis	Triangular fibro-cartilage
Recessus sacciformis	Membrana sacciformis
Lig. radio-carpeum volare	Anterior ligament of the radio-carpal joint
Lig. radio-carpeum dorsale	Posterior ligament of the radio-carpal joint
Lig. collaterale carpi ulnare	Internal lateral ligament of the wrist joint

B.N.A. Terminology.	Old Terminology.
Lig. collaterale carpi radiale	External lateral ligament of the wrist joint
Articulationes intercarpæ	Carpal joints
Lig. accessoria volaria	Palmar ligaments of the metacarpo-phalangeal joints
Lig. capitulorum (oss. metacarpalium) transversa	Transverse metacarpal ligament
Lig. collateralia	Lateral phalangeal ligaments

The Lower Extremity.

Lig. arcuatum	Subpubic ligament
Lig. sacro-tuberosum	Great sacro-sciatic ligament
Processus falciformis	Falciform process
Lig. sacro-spinosum	Small sacro-sciatic ligament
Labrum glenoidale	Cotyloid ligament
Zona orbicularis	Zonular band
Ligamentum iliofemorale	Y-shaped ligament
Lig. ischio-capsulare	Ischio-capsular band
Lig. pubo-capsulare	Pubo-femoral ligament
Lig. popliteum obliquum	Ligament of Winslow
Lig. collaterale fibulare	Long external lateral ligament
Lig. collaterale tibiale	Internal lateral ligament
Lig. popliteum arcuatum	Arcuate popliteal ligament
Meniscus lateralis	External semilunar cartilage
Meniscus medialis	Internal semilunar cartilage
Plica synovialis patellaris	Lig. mucosum
Plicæ alares	Ligamenta alaria
Articulatio tibio-fibularis	Superior tibio-fibular articulation
Lig. capituli fibulæ	Anterior and posterior superior tibio-fibular ligaments
Syndesmosis tibio-fibularis	Inferior tibio-fibular articulation
Lig. deltoideum	Internal lateral ligament of ankle
Lig. talo-fibulare anterius	Anterior fasciculus of external lateral ligament
Lig. talo-fibulare posterius	Posterior fasciculus of external lateral ligament
Lig. calcaneo-fibulare	Middle fasciculus of external lateral ligament
Lig. talo-calcaneum laterale	External calcaneo-astragaloid ligament
Lig. talo-calcaneum mediale	Internal calcaneo-astragaloid ligament
Lig. calcaneo-naviculare plantare	Inferior calcaneo-navicular ligament
Lig. talo-naviculare	Astragalo-scaphoid ligament
Pars calcaneo-navicularis } lig. bifurcatum	Superior calcaneo-scaphoid ligament
Pars calcaneo-cuboidea } lig. bifurcatum	Internal calcaneo-cuboid ligament

THE MUSCLES.

Muscles of the Back.

Superficial.

B.N.A. Terminology.	Old Terminology.
Levator scapulæ	Levator anguli scapulæ

Muscles of the Chest.

Serratus anterior	Serratus magnus

Muscles of Upper Extremity.

Biceps brachii	Biceps
Lacertus fibrosus	Bicipital fascia
Brachialis	Brachialis anticus
Triceps brachii	Triceps
Caput mediale	Inner head
Caput laterale	Outer head
Pronator teres	Pronator radii teres
Caput ulnare	Coronoid head
Brachio-radialis	Supinator longus
Supinator	Supinator brevis
Extensor carpi radialis longus	Extensor carpi radialis longior
Extensor carpi radialis brevis	Extensor carpi radialis brevior
Extensor indicis proprius	Extensor indicis
Extensor digiti quinti proprius	Extensor minimi digiti
Abductor pollicis longus	Extensor ossis metacarpi pollicis
Abductor pollicis brevis	Abductor pollicis
Extensor pollicis brevis	Extensor primi internodii pollicis
Extensor pollicis longus	Extensor secundi internodii pollicis
Lig. carpi transversum	Anterior annular ligament
Lig. carpi dorsale	Posterior annular ligament

Muscles of Lower Extremity.

Tensor fasciæ latæ	Tensor fasciæ femoris
Canalis adductorius (Hunteri)	Hunter's canal
Trigonum femorale (fossa Scarpæ major)	Scarpa's triangle
Canalis femoralis	Crural canal
Annulus femoralis	Crural ring
M. quadriceps femoris—	Quadriceps—
Rectus femoris	Rectus femoris
Vastus lateralis	Vastus externus
Vastus intermedius	Crureus
Vastus medialis	Vastus internus
M. articularis genu	Subcrureus
Tibialis anterior	Tibialis anticus

B.N.A. Terminology.	Old Terminology.
Tendo calcaneus	Tendo Achillis
Tibialis posterior	Tibialis posticus
Quadratus plantæ	Accessorius
Lig. transversum cruris	Upper anterior annular ligament
Lig. cruciatum cruris	Lower anterior annular ligament
Lig. laciniatum	Internal annular ligament
Retinaculum musculorum peronæorum superius Retinaculum musculorum peronæorum inferius	External annular ligament

Axial Muscles.

Muscles of the Back.

Serratus posterior superior	Serratus posticus superior
Serratus posterior inferior	Serratus posticus inferior
Splenius cervicis	Splenius colli
Sacro-spinalis	Erector spinæ
Ilio-costalis—	**Ilio-costalis—**
Lumborum	Sacro-lumbalis
Dorsi	Accessorius
Cervicis	Cervicalis ascendens
Longissimus—	**Longissimus—**
Dorsi	Dorsi
Cervicis	Transversalis cervicis
Capitis	Trachelo-mastoid
Spinalis—	**Spinalis—**
Dorsi	Dorsi
Cervicis	Colli
Capitis	Capitis
Semispinalis—	**Semispinalis—**
Dorsi	Dorsi
Cervicis	Colli
Capitis	Complexus
Multifidus	Multifidus spinæ

Muscles of Head and Neck.

Epicranius	Occipito-frontalis
Galea aponeurotica	Epicranial aponeurosis
Procerus	Pyramidalis nasi
Pars transversa (nasalis)	Compressor naris
Pars alaris (nasalis)	Dilatores naris
Auricularis anterior	Attrahens aurem
Auricularis posterior	Retrahens aurem
Auricularis superior	Attollens aurem
Orbicularis oculi	Orbicularis palpebrarum
Pars lacrimalis	Tensor tarsi

B.N.A. Terminology.	Old Terminology.
Triangularis	Depressor anguli oris
Quadratus labii superioris—	
Caput zygomaticum	Zygomaticus minor
Caput infraorbitale	Levator labii superioris
Caput angulare	Levator labii superioris alæque nasi
Zygomaticus	Zygomaticus major
Caninus	Levator anguli oris
Quadratus labii inferioris	Depressor labii inferioris
Mentalis	Levator menti
Platysma	Platysma myoides
Sterno-thyreoid	Sterno-thyroid
Thyreo-hyoid	Thyro-hyoid

Muscles and Fascia of the Orbit.

Fascia bulbi	Capsule of Tenon
Septum orbitale	Palpebral ligaments
Rectus lateralis	Rectus externus
Rectus medialis	Rectus internus

Muscles of the Tongue.

Genio-glossus	Genio-hyo-glossus
Longitudinalis superior	Superior lingualis
Longitudinalis inferior	Inferior lingualis
Transversus linguæ	Transverse fibres
Verticalis linguæ	Vertical fibres

Muscles of the Pharynx.

Pharyngo-palatinus	Palato-pharyngeus
M. uvulæ	Azygos uvulæ
Levator veli palatini	Levator palati
Tensor veli palatini	Tensor palati
Glosso-palatinus	Palato-glossus

Deep Lateral Muscles of Neck.

Scalenus anterior	Scalenus anticus
Scalenus posterior	Scalenus posticus
Longus capitis	Rectus capitis anticus major
Rectus capitis anterior	Rectus capitis anticus minor

Muscles of Thorax.

Transversus thoracis	Triangularis sterni
Diaphragma	Diaphragm
Crus mediale Crus intermedium Crus laterale	Crura and origins from arcuate ligaments
Arcus lumbo-costalis medialis (Halleri)	Ligamentum arcuatum internum
Arcus lumbo-costalis lateralis (Halleri)	Ligamentum arcuatum externum

Muscles of the Abdomen.

B.N.A. Terminology.	Old Terminology.
Ligamentum inguinale (Pouparti)	Poupart's ligament
Ligamentum lacunare (Gimbernati)	Gimbernat's ligament
Fibræ intercrurales	Intercolumnar fibres
Ligamentum inguinale reflexum (Collesi)	Triangular fascia
Annulus inguinalis subcutaneus	External abdominal ring
Crus superius	Internal pillar
Crus inferius	External pillar
Falx aponeurotica inguinalis	Conjoined tendon
M. transversus abdominis	Transversalis muscle
Linea semicircularis (Douglasi)	Fold of Douglas
Annulus inguinalis abdominalis	Internal abdominal ring

Perineum and Pelvis.

Transversus perinei superficialis	Transversus perinei
M. sphincter urethræ membranaceæ	Compressor urethræ
Diaphragma urogenitale	Deep transverse muscle and sphincter urethræ
Fascia diaphragmatis urogenitalis superior	Deep layer of triangular ligament
Fascia diaphragmatis urogenitalis inferior	Superficial layer of the triangular ligament
Arcus tendineus fasciæ pelvis	White line of pelvis
Ligamenta puboprostatica	Anterior and lateral true ligaments of bladder
Fascia diaphragmatis pelvis superior	Visceral layer of pelvic fascia
Fascia diaphragmatis pelvis inferior	Anal fascia

THE NERVOUS SYSTEM.

Medulla Spinalis.	Spinal Cord.
Fasciculus anterior proprius (Flechsig)	Anterior ground or basis bundle
Fasciculus lateralis proprius	Lateral ground bundle
Nucleus dorsalis	Clarke's column
Pars thoracalis	Dorsal part of spinal cord
Sulcus intermedius posterior	Paramedian furrow
Columnæ anteriores, etc.	Anterior grey column
Fasciculus cerebro-spinalis anterior	Direct pyramidal tract
Fasciculus cerebro-spinalis lateralis (pyramidalis)	Crossed pyramidal tract
Fasciculus cerebello-spinalis	Direct cerebellar tract
Fasciculus antero-lateralis superficialis	Gowers' tract

The Brain or **Encephalon** is divided into parts as follows :—

- **RHOMBENCEPHALON** = Myelencephalon (medulla) (after-brain) / Metencephalon (pons and cerebellum) (hind-brain) } Posterior primary vesicle.
- **CEREBRUM** = **MESENCEPHALON** (mid-brain, peduncles, corpora quadrigemina, etc.)—Middle primary vesicle.
  - **PROSENCEPHALON** (fore-brain)
    - **Diencephalon** = Thalamencephalon (inter-brain)
      - Thalamus (optic thalamus).
      - Metathalamus (geniculate bodies).
      - Epithalamus (pineal body).
    - Mammillary portion of hypothalamus (subthalamic region).
    - Posterior part of 3rd ventricle.
    - **Telencephalon**
      - Optic portion of hypothalamus (hypophysis).
      - Optic nerves.
      - Anterior part of 3rd ventricle.
    - Pallium (cortex cerebri).
      - Lateral ventricles.

Brain.

B.N.A. Terminology.	Old Terminology.
Rhombencephalon	
Eminentia medialis	Eminentia teres
Ala cinerea	Trigonum vagi
Ala acustica	Trigonum acusticum
Nucleus nervi abducentis	Nucleus of 6th nerve
Nuclei n. acustici	Auditory nucleus
Fasciculus longitudinalis medialis	Posterior longitudinal bundle
Corpus trapezoideum	Corpus trapezoides
Incisura cerebelli anterior	Semilunar notch (of cerebellum)
Incisura cerebelli posterior	Marsupial notch
Sulcus horizontalis cerebelli	Great horizontal fissure
Lobulus centralis	Lobus centralis
Folium vermis	Folium cacuminis
Tuber vermis	Tuber valvulæ
Lobulus quadrangularis	Quadrate lobule
Brachium conjunctivum cerebelli	Superior cerebellar peduncle
Lobulus semilunaris superior	Postero-superior lobule
Lobulus semilunaris inferior	Postero-inferior lobule
Cerebrum	
Pedunculus cerebri	Crus cerebri
Colliculus superior	Anterior corpus quadrigeminum
Colliculus inferior	Posterior corpus quadrigeminum
Aqueductus cerebri	Iter e tertio ad quartum ventriculum, or aqued. of Sylvius
Foramen interventriculare	Foramen of Monro
Hypothalamus	Subthalmic region
Sulcus hypothalamicus	Sulcus of Monro
Massa intermedia	Middle commissure
Fasciculus thalamo-mammillaris	Bundle of Vicq d'Azyr
Pars opercularis	Pars basilaris
Thalamus	Optic thalamus
Pallium	Cortex cerebri
Gyri transitivi	Annectant gyri
Fissura cerebri lateralis	Fissure of Sylvius
Gyrus temporalis superior	First temporal gyrus
Gyrus temporalis medius	Second temporal gyrus
Gyrus temporalis inferior	Third temporal gyrus
Sulcus centralis (Rolandi)	Fissure of Rolando
Sulcus temporalis superior	Parallel sulcus
Sulcus temporalis medius	Second temporal sulcus
Sulcus circularis	Limiting sulcus of Reil
Sulcus temporalis inferior	Occipito-temporal sulcus
Gyrus fusiformis	Occipito-temporal convolution
Sulcus interparietalis	Intraparietal sulcus
Sulcus corporis callosi	Callosal sulcus
Sulcus cinguli	Calloso-marginal fissure
Fissura hippocampi	Dentate fissure
Gyrus cinguli	Callosal convolution

B.N.A. Terminology.	Old Terminology.
Stria terminalis	Tænia semicircularis
Trigonum collaterale	Trigonum ventriculi
Hippocampus	Hippocampus major
Digitationes hippocampi	Pes hippocampi
Fascia dentata hippocampi	Gyrus dentatus
Columna fornicis	Anterior pillar of fornix
Septum pellucidum	Septum lucidum
Inferior cornu	Descending horn of lateral ventricle
Commissura hippocampi	Lyra
Nucleus lentiformis	Lenticular nucleus
Pars frontalis capsulæ internæ	Anterior limb (of internal capsule)
Pars occipitalis capsulæ internæ	Posterior limb (of internal capsule)
Radiatio occipito-thalamica	Optic radiation
Radiatio corporis callosi	Radiation of corpus callosum
Pars frontalis	Forceps minor
Pars occipitalis	Forceps major

Membranes of Brain.

Cisterna cerebello-medullaris	Cisterna magna
Cisterna interpeduncularis	Cisterna basalis
Granulationes arachnoideales	Pacchionian bodies
Tela chorioidea ventriculi tertii	Velum interpositum
Tela chorioidea ventriculi quarti	Tela choroidea inferior

Cerebral Nerves.

N. oculomotorius	Third nerve
N. trochlearis	Fourth nerve
N trigeminus	Fifth nerve
Ganglion semilunare (Gasseri)	Gasserian ganglion
N. naso-ciliaris	Nasal nerve
N. maxillaris	Superior maxillary nerve
N. meningeus (medius)	Recurrent meningeal nerve
N. zygomaticus	Temporo-malar nerve
Rami alveolares superiores posteriores	Posterior superior dental
Rami alveolares superiores medii	Middle superior dental
Rami alveolares superiores anteriores	Anterior superior dental
Ganglion spheno-palatinum	Meckel's ganglion
N. palatinus medius	External palatine nerve
N. mandibularis	Inferior maxillary nerve
Nervus spinosus	Recurrent nerve
N. alveolaris inferior	Inferior dental
N. abducens	Sixth nerve
N. facialis	Seventh nerve
N. intermedius	Pars intermedia of Wrisberg
N. acusticus	Eighth or auditory nerve

B.N.A. Terminology.	Old Terminology.
Ganglion superius	Jugular ganglion of 9th nerve
N. recurrens	Recurrent laryngeal nerve
Ganglion jugulare	Ganglion of root } of vagus
Ganglion nodosum	Ganglion of trunk } of vagus
Plexus œsophageus anterior }	Plexus gulæ
Plexus œsophageus posterior }	
Nervus accessorius	Spinal accessory
Ramus internus	Accessory portion of spinal accessory nerve
Ramus externus	Spinal portion

Spinal Nerves.

Rami posteriores	Posterior primary divisions
Rami anteriores	Anterior primary divisions
N. cutaneus colli	Superficial cervical nerve
Nn. supraclaviculares anteriores	Suprasternal nerves
Nn. supraclaviculares medii	Supraclavicular nerves
Nn. supraclaviculares posteriores	Supra-acromial nerves
N. dorsalis scapulæ	Nerve to the rhomboids
Nn. intercosto-brachiales	Intercosto-humeral nerve
N. thoracalis longus	Nerve of Bell
N. thoraco-dorsalis	Long subscapular nerve
N. cutaneus brachii medialis	Lesser internal cutaneous nerve
N. cutaneus brachii lateralis	Cutaneous branch of circumflex nerve
Fasciculus lateralis	Outer cord (of plexus)
Fasciculus medialis	Inner cord
N. cutaneus antibrachii lateralis	Cutaneous branch of musculo-cutaneous nerve
N. cutaneus antibrachii medialis	Internal cutaneous nerve
Ramus volaris	Anterior branch
Ramus ulnaris	Posterior branch
N. cutaneus antibrachii dorsalis	External cutaneous branch of musculo-spiral
N. axillaris	Circumflex nerve
N. interosseus volaris	Anterior interosseous
Ramus palmaris N. mediani	Palmar cutaneous branch of the median nerve
Nn. digitales volares proprii	Collateral palmar digital branches of median nerve
Ramus dorsalis manus	Dorsal cutaneous branch of ulnar nerve
Ramus cutaneus palmaris	Palmar cutaneous branch of ulnar nerve
N. radialis	Musculo-spiral nerve
N. cutaneus brachii posterior	Internal cutaneous branch of musculo-spiral nerve
N. cutaneus antibrachii dorsalis	External cutaneous branches of musculo-spiral nerve

B.N.A. Terminology.	Old Terminology.
N. radialis (*contd.*)—	Musculo-spiral nerve (*contd.*)—
Ramus superficialis	Radial nerve
N. interosseus dorsalis	Posterior interosseous nerve
Nn. digitales dorsales	Dorsal digital nerves
N. ilio-hypogastricus	Ilio-hypogastric nerve
Ramus cutaneus lateralis	Iliac branch of ilio-hypogastric nerve
Ramus cutaneus anterior	Hypogastric branch of ilio-hypogastric nerve
N. genito-femoralis	Genito-crural nerve
N. lumbo-inguinalis	Crural branch of genito-crural nerve
N. spermaticus externus	Genital branch of genito-crural nerve
N. cutaneus femoris lateralis	External cutaneous nerve
N. femoralis	Anterior crural nerve
N. saphenus	Long saphenous nerve
Ramus infrapatellaris	Patellar branch of long saphenous nerve
N. ischiadicus	Great sciatic nerve
N. peronæus communis	External popliteal nerve
Ramus anastomoticus peronæus	Nervus communicans fibularis
N. peronæus superficialis	Musculo-cutaneous nerve
N. peronæus profundus	Anterior tibial nerve
N. tibialis	Internal popliteal nerve
N. cutaneus suræ medialis	Nervus communicans tibialis
N. suralis	Short saphenous nerve
N. plantaris medialis	Internal plantar
N. plantaris lateralis	External plantar
N. pudendus	Pudic nerve

THE HEART AND BLOOD VESSELS.

Heart.

Atrium	Auricle
Auricula cordis	Auricular appendix
Incisura cordis	Notch at apex of heart
Trabeculæ carneæ	Columnæ carneæ
Tuberculum intervenosum	Intervenous tubercle of Lower
Sulcus longitudinalis anterior	Anterior interventricular groove
Sulcus coronarius	Auriculo-ventricular groove
Limbus fossæ ovalis	Annulus ovalis
Valvula venæ cavæ	Eustachian valve
Valvula sinus coronarii	Valve of Thebesius

Arteries.

B.N.A. Terminology.	Old Terminology.
Sinus aortæ	Sinuses of Valsalva
A. profunda linguæ	Ranine artery
A. maxillaris externa	Facial artery
A. alveolaris inferior	Inferior dental artery
Ramus meningeus accessorius	Small meningeal artery
A. buccinatoria	Buccal artery
A. alveolaris superior posterior	Posterior dental artery
Aa. alveolares superiores anteriores	Anterior superior dental arteries
Ramus carotico-tympanicus	Tympanic branch of int. carotid
A. chorioidea	Anterior choroidal artery
A. auditiva interna	Auditory artery
Rami ad pontem	Transverse arteries (branches of Basilar artery)
A. pericardiaco-phrenica	Arteria comes nervi phrenici
Rami intercostales (A. mammaria interna)	Anterior intercostal arteries
Truncus thyreo-cervicalis	Thyroid axis
A. transversa scapulæ	Suprascapular artery
A. intercostalis suprema	Superior intercostal
A. transversa colli	Transversalis colli
A. thoracalis suprema	Superior thoracic artery
A. thoraco-acromialis	Acromio-thoracic artery
A. thoracalis lateralis	Long thoracic artery
A. circumflexa scapulæ	Dorsalis scapulæ
A. profunda brachii	Superior profunda
A. collateralis radialis	Anterior branch of superior profunda
A. collateralis ulnaris superior	Inferior profunda
A. collateralis ulnaris inferior	Anastomotica magna
Ramus carpeus volaris	Anterior radial carpal
Ramus carpeus dorsalis	Posterior radial carpal
Aa. metacarpeæ dorsales	Dorsal interosseous arteries
A. volaris indicis radialis	Radialis indicis
Arcus volaris superficialis	Superficial palmar arch
Arcus volaris profundus	Deep palmar arch
A. interossea dorsalis	Posterior interosseous artery
A. interossea recurrens	Posterior interosseous recurrent artery
A. interossea volaris	Anterior interosseous artery
Ramus carpeus dorsalis	Posterior ulnar carpal
Ramus carpeus volaris	Anterior ulnar carpal
Aa. digitales volares communes	Palmar digital arteries
Aa. digitales volares propriæ	Collateral digital arteries
Arteriæ intestinales	Intestinal branches of sup. mesenteric
A. suprarenalis media	Middle capsular artery
A. hypogastrica	Internal iliac artery
A. umbilicalis	Obliterated hypogastric
A. pudenda interna	Internal pudic artery
A epigastrica inferior	Deep epigastric artery

B.N.A. Terminology.	Old Terminology.
A. spermatica externa	Cremasteric artery
Aa. pudendæ externæ	Superficial and deep external pudic arteries
A. circumflexa femoris medialis	Internal circumflex artery
A. circumflexa femoris lateralis	External circumflex artery
A. genu suprema	Anastomotica magna
A. genu superior lateralis	Superior external articular artery
A. genu superior medialis	Superior internal articular artery
A. genu media	Azygos articular artery
A. genu inferior lateralis	Inferior external articular artery
A. genu inferior medialis	Inferior internal articular artery
A. malleolaris anterior lateralis	External malleolar artery
A. malleolaris anterior medialis	Internal malleolar artery
A. peronæa	Peroneal artery
Ramus perforans	Anterior peroneal artery
A. malleolaris posterior lateralis	Posterior peroneal artery
A. malleolaris posterior medialis	Internal malleolar artery
Rami calcanei laterales	External calcanean artery
Rami calcanei mediales	Internal calcanean artery
A. plantaris medialis	Internal plantar artery
A. plantaris lateralis	External plantar artery
Aa. metatarseæ plantares	Digital branches
Aa. digitales plantares	Collateral digital branches

Veins.

V. cordis magna	Great cardiac vein
V. obliqua atrii sinistri	Oblique vein of Marshall
Lig. venæ cavæ sinistræ	Vestigial fold of Marshall
Vv. cordis minimæ	Veins of Thebesius
Sinus transversus	Lateral sinus
Confluens sinuum	Torcular Herophili
Plexus basilaris	Basilar sinus
Sinus sagittalis superior	Superior longitudinal sinus
Sinus sagittalis inferior	Inferior longitudinal sinus
Spheno-parietal sinus	Sinus alæ parvæ
V. cerebri internæ	Veins of Galen
V. cerebri magna	Vena magna Galeni
V. terminalis	Vein of the corpus striatum
V. basalis	Basilar vein
V. transversa scapulæ	Suprascapular vein
V. thoraco-acromialis	Acromio-thoracic vein
Vv. transversæ colli	Transversalis colli veins
V. thoracalis lateralis	Long thoracic vein
V. azygos	Vena azygos major
V. hemiazygos	Vena azygos minor inferior
V. hemiazygos accessoria	Vena azygos minor superior
V. hypogastrica	Internal iliac vein
V. epigastrica inferior	Deep epigastric vein
V. saphena magna	Internal saphenous vein
V. saphena parva	External saphenous vein

Lymphatics.

B.N.A. Terminology.	Old Terminology.
Cisterna chyli	Receptaculum chyli

THE VISCERA.

Digestive Apparatus.

Arcus glosso-palatinus	Anterior pillar of fauces
Arcus pharyngo-palatinus	Posterior pillar of fauces
Gl. lingualis anterior	Gland of Nuhn
Ductus submaxillaris	Wharton's duct
Gl. parotis accessoria	Socia parotidis
Ductus parotideus (Stenonis)	Stenson's duct
Dentes præmolares	Bicuspid teeth
Dens serotinus	Wisdom tooth
Papillæ vallatæ	Circumvallate papillæ
Recessus pharyngeus	Lateral recess of pharynx
Tela submucosa	Pharyngeal aponeurosis
Plicæ circulares	Valvulæ conniventes
Gl. intestinales	Crypts of Lieberkuhn
Valvula coli	Ileo-cæcal valve
Columnæ rectales	Columns of Morgagni
Plicæ transversales recti	Valves of Houston
Valvula spiralis	Valves of Heister
Noduli lymphatici aggregati (Peyeri)	Peyer's patches
Intestinum jejunum	Jejunum
Intestinum ileum	Ileum
Noduli lymphatici lienales (Malpighii)	Malpighian corpuscles

Respiratory Apparatus.

Larynx	
Prominentia laryngea	Adam's apple
Incisura thyreoidea superior	Superior thyroid notch
M. ary-epiglotticus	Aryteno-epiglottidean muscle
M. vocalis	Internal thyro-arytenoid muscle
M. thyreo-epiglotticus	Thyro-epiglottidean muscle
Appendix ventriculi laryngis	Laryngeal sac
Plica vocalis	True vocal cord
Plica ventricularis	False vocal cord
Ligamentum ventriculare	Superior thyro-arytenoid ligament
Ligamentum vocale	Inferior thyro-arytenoid ligament
Glottis	Glottis vera
Rima vestibuli	Glottis spuria
Cartilago thyreoidea	Thyroid cartilage

B.N.A. Terminology.	Old Terminology.
Membrana hyo-thyreoidea	Thyro-hyoid membrane
Cartilago corniculata (Santorini)	Cartilage of Santorini
Tuberculum epiglotticum	Cushion of epiglottis
Pars intermembranacea (rimæ glottidis)	Glottis vocalis
Pars intercartilaginea (rimæ glottidis)	Glottis respiratoria
Conus elasticus (membranæ elasticæ larynges)	Crico-thyroid membrane
Glandula thyreoidea	Thyroid gland
Glomus caroticum	Intercarotid gland or body
Nose	
Concha nasalis suprema (Santorini)	Highest turbinate bone
Concha nasalis superior	Superior turbinate bone
Concha nasalis media	Middle turbinate bone
Concha nasalis inferior	Inferior turbinate bone

Urogenital Apparatus.

Corpuscula renis	Malpighian corpuscles
Paradidymis	Organ of Giraldés
Appendix testis	Hydatid of Morgagni (male)
Ductus deferens	Vas deferens
Gl. urethrales	Glands of Littré
Glandula bulbo-urethralis (Cowperi)	Cowper's gland
Folliculi oophori vesiculosi	Graafian follicles
Cumulus oophorus	Discus proligerus
Tuba uterina	Fallopian tube
Epoophoron	Parovarium
Appendices vesiculosi	Hydatids of Morgagni (female)
Ductus epoophori longitudinalis	Gärtner's duct
Orificium internum uteri	Internal os (of uterus)
Orificium externum	External os
Processus vaginalis	Canal of Nuck
Glandula magna vestibuli	Bartholin's gland

Peritoneum.

Bursa omentalis	Lesser peritoneal sac
Foramen epiploicum	Foramen of Winslow
Lig. phrenico-colicum	Costo-colic ligament
Excavatio recto-uterina (cavum Douglasi)	Pouch of Douglas
Lig. gastro-lienale	Gastro-splenic omentum

SENSE ORGANS.

The Eye.

Sclera	Sclerotic coat
Lamina elastica anterior (Bowmani)	Bowman's membrane

B.N.A. Terminology.	Old Terminology.
Lamina elastica posterior (Descemeti)	Descemet's membrane
Spatia anguli iridis	Spaces of Fontana
Angulus iridis	Irido-corneal junction
Zonula ciliaris	Zonule of Zinn
Septum orbitale	Palpebral ligament
Fascia bulbi	Capsule of Tenon
Commissura palpebrarum lateralis	External canthus
Commissura palpebrarum medialis	Internal canthus
Tarsus superior	Superior tarsal plate
Tarsus inferior	Inferior tarsal plate
Lig. palpebrale mediale	Internal tarsal ligament
Raphe palpebralis lateralis	External tarsal ligament
Tarsal glands	Meibomian glands

The Ear.

Canalis semicircularis lateralis	External semicircular canal
Ductus reuniens	Canalis reuniens
Ductus cochlearis	Membranous cochlea
Recessus sphericus	Fovea hemispherica
Recessus ellipticus	Fovea hemi-elliptica
Paries jugularis	Floor of tympanum
Paries labyrinthica	Inner wall
Fenestra vestibuli	Fenestra ovalis
Fenestra cochleæ	Fenestra rotunda
Paries mastoidea	Posterior wall
Antrum tympanicum	Mastoid antrum
Paries carotica	Anterior wall
Processus lateralis	Processus brevis (of malleus)
Processus anterior	Processus gracilis

MANUAL
OF
PRACTICAL ANATOMY.

HEAD AND NECK.

THE dissectors of the Head and Neck begin work as soon as the subject is brought into the room. During the first three days, whilst the body is in the lithotomy posture, they dissect the face, the anterior part of the eyelids, the superficial part of the nose, and the anterior part of the scalp. During the following five days, when the body is lying on its back, they dissect the posterior triangle, and complete the dissection of the scalp.

It is only by dissecting the face at this period, whilst the parts are in good condition, that the dissector can gain any satisfactory idea of its component parts; and it is essential that the contents of the posterior triangle, which is such an important surgical region, should be displayed before the dissector of the arm has disturbed its posterior boundary.

The *first day* should be devoted to the examination of the anterior part of the frontal region of the head and the face, the study of the surface anatomy of the ocular appendages, the reflection of the skin and the cleaning of the superficial muscles of the face and anterior part of the scalp. On the *second day* the dissectors should display the superficial surface of the parotid gland; they should also find and clean the superficial vessels and nerves, and trace them to

their terminations. On the *third day* the superficial muscles must be reflected, and the deeper vessels and nerves must be exposed and cleaned, and the auricle should be examined and dissected. On the *fourth day* the body is placed upon its back, and the dissectors should commence the dissection of the posterior triangle of the neck; they must complete that part of the dissection in three days. On the *seventh day* they should complete the examination of the scalp. The *eighth day* should be devoted to a final study of the brachial plexus, in association with the dissectors of the upper extremity.

FACE AND FRONTAL REGION OF HEAD.

The dissectors should commence the study of the face and frontal region by an examination of the bony prominences and ridges in the area to be dissected.

In the centre of the facial area is the prominent outer portion of the nose, consisting of a lower mobile part, formed mainly by skin and cartilage, and an upper rigid portion, formed by the nasal bones and the frontal processes of the maxillæ. At the sides of the nose are the sockets for the eyeballs, each of which is bounded above by the supra-orbital margin of the frontal bone and below by the orbital margins of the maxilla and the zygomatic bone (O.T. malar). The supra- and infra-orbital margins meet laterally in the region of the cheek bone (zygomatic). From the posterior part of the zygomatic bone, the zygomatic arch, formed partly by the zygomatic and partly by the temporal bone, extends barkwards to the ear. Above the zygomatic arch is the region of the temporal fossa, which is bounded superiorly by the temporal line. The line terminates anteriorly in the lateral part of the supra-orbital margin. Above the medial part of the supra-orbital margin the superciliary arch can be felt, and at a higher level, above the lateral part of the supra-orbital margin, lies the frontal tuberosity. The region above the nose and between the medial ends of the superciliary arches is the *glabella*.

Below the zygomatic arch lies the ramus of the mandible, covered by the masseter muscle; and extending forwards from the lower end of the ramus is the body of the mandible. A line dropped vertically through the junction of the medial

third with the lateral two-thirds of the supra-orbital margin, will cut through the supra-orbital notch of the frontal bone, the infra-orbital foramen of the maxilla, and the mental foramen of the mandible, all three of which may be felt if firm pressure is made in the proper situations. The first, which lies in the supra-orbital margin, transmits the supra-orbital vessels and nerve. The second is placed about half an inch below the infra-orbital margin; it transmits the infra-orbital vessels and nerve. The third lies midway between the second premolar tooth of the mandible and the lower border of the mandible; it transmits the mental branches of the inferior alveolar vessels and nerve.

After the bony points of the region have been studied, the surface anatomy of the ocular appendages should be examined. Under this head are included—(1) the eyebrows; (2) the eyelids; (3) the conjunctiva.

The *eyebrows* are two curved tegumentary projections placed over the supra-orbital arches of the frontal bone; they intervene between the forehead above and the ocular regions below. The short stiff hairs which spring from the eyebrows have a lateral inclination.

The *eyelids* (palpebræ) are the semilunar curtains provided for the protection of each eyeball. The upper lid is the longer and much the more movable of the two. When the eye is open, the margins of the two lids are slightly concave and the interval between them, *rima palpebrarum*, is elliptical in outline. When the eye is closed, and the margins of the lids are in apposition, the rima palpebrarum is reduced to a nearly horizontal line. Owing to the greater length and mobility of the upper lid, the rima, in the closed condition, is placed at the level of the lower border of the cornea, which is the transparent front part of the eyeball.

At the extremities of the rima palpebrarum the eyelids meet and form the *palpebral commissures.* Immediately lateral to the medial commissure the rima expands into a small triangular space, called the *lacus lacrimalis.* If the dissector now examines the free margins of the lids he will note that, to the lateral side of the lacus lacrimalis, they are flat, and that in each lid the *cilia* or eyelashes project from the anterior border, whilst the tarsal glands open, by a series of minute apertures, along the posterior border, a distinct interval intervening between the cilia and the

mouths of the glands. On the other hand, the small portion of the margin of each eyelid which bounds the lacus lacrimalis is more horizontal in direction and somewhat rounded. It is destitute both of eyelashes and of tarsal glands. At the very point where the eyelashes in each eyelid cease, and the palpebral margin becomes rounded, a small eminence, with a central perforation, will be seen. The

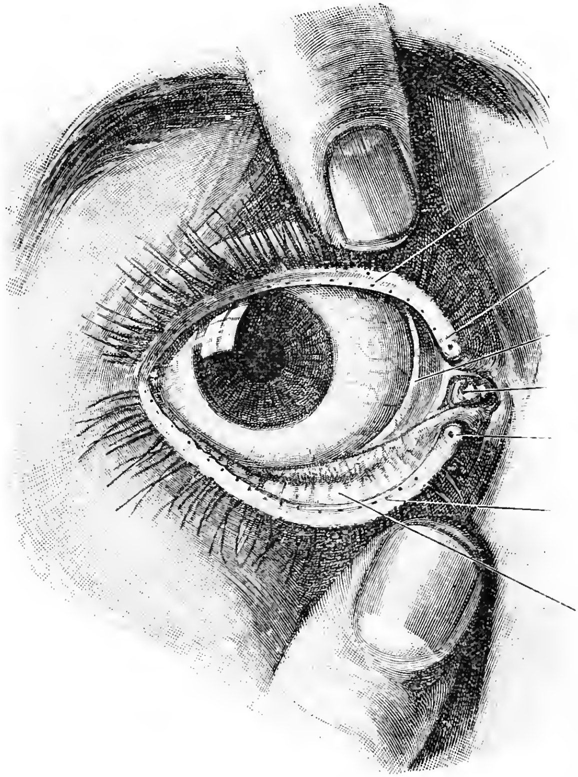

FIG. 1.—Eyelid slightly everted to show the Conjunctiva (enlarged).

eminence is the *papilla lacrimalis*, whilst the perforation, called the *punctum lacrimale*, is the mouth of a *lacrimal duct*, which conveys away the tears. Endeavour to pass a bristle into each of the orifices. The upper duct at first ascends, whilst the lower one descends, and then both run horizontally to the lacrimal sac, which lies in a depression in the medial wall of the orbit.

The *conjunctiva* is the membrane which lines the deep surfaces of the lids. It is reflected from them on to the

anterior aspect of the eyeball. At the margins of the lids it is continuous with the skin, whilst, through the puncta lacrimalia and the lacrimal ducts, it becomes continuous with the lining membrane of the lacrimal sac. The line of reflection of the conjunctiva from each of the eyelids on to the eyeball is termed a *fornix conjunctivæ*. Owing to the greater vertical extent of the upper lid, the conjunctival recess between the upper lid and the eyeball is larger than that behind the lower lid. The conjunctiva is loosely connected with the eyelids on the one hand, and with the sclera, or white part of the eyeball, on the other. Over the cornea the membrane becomes thinned down to a mere epithelial covering, which forms the epithelium of the cornea.

In connection with the conjunctiva, the *plica semilunaris* and the *caruncula lacrimalis* must be examined. The caruncula is the reddish, fleshy-looking elevation which occupies the centre of the lacus lacrimalis. From its surface a few minute hairs project. The plica semilunaris is of interest because it is the rudimentary representative, in the human eye, of the membrana nictitans, or third eyelid, found in many animals. It is a small vertical fold of conjunctiva, which is placed immediately to the lateral side of the caruncula, and it slightly overlaps the eyeball at that point (Fig. 1).

Dissection.—Distend the eyelids slightly by placing a little tow or cotton wool, steeped in preservative solution, in the conjunctival sac; then stitch the margins of the lids together. Distend the cheeks and lips slightly by placing tow or cotton wool, steeped in preservative solution, in the vestibule of the mouth—that is, between the cheeks and lips externally and the teeth and gums internally; then stitch the red margins of the lips together.

Reflect the skin by means of three incisions, a median longitudinal and two transverse. Commence the median incision midway between the root of the nose and the external occipital protuberance, carry it forwards to the forehead and then downwards along the median line of the forehead, the nose and the lips, to the tip of the chin. Commence the upper horizontal incision at the level of the rima palpebrarum; carry it laterally from the longitudinal incision to the medial commissure, then round the margins of the rima to the lateral commissure, and, finally, backwards to the ear. The lower horizontal incision should run from the angle of the mouth to the posterior border of the ramus of the mandible. Reflect the upper and middle flaps and leave them attached posteriorly. Reflect the lower flap downwards to the lower border of the mandible. Note, whilst reflecting the skin, that many of the superficial fibres of the facial muscles are implanted into its deep surface. It is

those fibres which tend to displace the margins of wounds of the face, and necessitate the application of numerous and firmly tied sutures in order to secure quick and accurate union. Whilst reflecting the skin the dissector must be careful to keep his knife playing against its deep surface; otherwise he is certain to injure the sphincter muscle of the eyelids, and the superficial extrinsic muscles of the ear which lie in the temporal region.

After the skin is reflected, clean the superficial muscles. That which will first attract attention is the orbicularis oculi, around the orbit. Above the orbicularis oculi is the frontal belly of the epicranial muscle. To the medial side of the orbicularis oculi lie the muscles of the nose. Below the eye the muscles of the upper lip pass downwards to the orbicularis oris and the mouth. Passing forwards and upwards, over the posterior part of the lower border of the mandible, are the upper and posterior fibres of the platysma, and more medially are the muscles of the lower lip (Fig. 2).

Commence with the *orbicularis oculi* (O.T. orbicularis palpebrarum), which lies in and around the region of the eyelids. Pull the eyelids laterally and note a prominent cord-like band which extends from the frontal process of the maxilla to the medial commissure, where it becomes continuous with both eyelids; it is the *medial palpebral ligament* (O.T. internal tarsal ligament). A somewhat similar band, the *lateral palpebral raphe* (O.T. external tarsal ligament), extends from the lateral commissure to the zygomatic bone. After the medial palpebral ligament has been recognised, clean first the thicker *orbital part* of the orbicularis oculi, which covers the superficial bony boundaries of the orbit, and then the thinner *palpebral portion*, which lies in the eyelids. The palpebral part is not only thin but also pale, and its fibres, in each eyelid, sweep in gentle curves from the medial palpebral ligament to the lateral palpebral raphe, gaining attachment to both.

Next clean the *orbicularis oris*, which surrounds the mouth, and take care not to injure the other muscles of the lips which blend with the margins of the orbicularis oris. Attempt to define the *depressor septi nasi* which springs from the middle of the upper border of the orbicularis oris and is inserted into the lower part of the septum of the nose (Fig. 2).

After the two orbicular muscles have been cleaned, turn to the *frontal belly of the epicranius*, which lies above the orbicularis oculi. Its fibres run upwards and backwards from the orbicularis oculi, with which it blends, to the tendinous sheet called the galea aponeurotica, which covers the vertex of the skull and connects the frontal belly with the occipital belly of the muscle. The edge of the knife must be kept parallel with the fibres of the muscle, and as the cleaning proceeds avoid injuring the branches of the supra-orbital nerve and artery which pierce the muscle. From the medial margin of the frontal belly of the epicranius trace a small bundle of muscle fibres, called the *procerus*, downwards to the dorsum of the nose, and at the same time secure the supra-trochlear nerve and the frontal branch of the ophthalmic artery which pierce the muscle at the medial part of the upper margin of the orbit. Below the procerus secure the *angular head of the quadratus labii superioris*, a muscular slip which springs from the frontal process of the

maxillary bone, and trace it downwards to the orbicularis oris, but avoid injury to the angular vein which lies on its superficial surface. Medial to the angular head of the quadratus labii superioris find and clean the *pars transversa* of the *musculus nasalis*, which lies across the lower part of the bridge of the nose. Below the pars transversa it may be possible to display the *pars alaris* which passes from the maxilla to the ala of the nose.

Now turn to the lower border of the mandible and clean the platysma, a broad thin sheet of muscle which ascends from the neck. Its anterior fibres are inserted into the anterior part of the lower border of the mandible. The posterior fibres ascend across the mandible, then they turn forwards to the angle of the mouth, as the *risorius*. Above and in front of the risorius find the *zygomaticus*, a slender muscle which descends from the zygomatic bone to the angle of the mouth, where it blends with the orbicularis oris. Now follow the angular vein downwards and backwards. At the lower margin of the orbit it becomes the anterior facial vein ; follow that vein downwards and backwards to the point where it disappears under cover of the zygomaticus. Below and in front of the anterior facial vein the terminal part of the external maxillary artery may be found on the superficial surface of the quadratus labii superioris, but it may lie deep to that muscle. After the anterior facial vein has been cleaned, in the area indicated, raise the lower fibres of the orbicularis oculi and reflect them towards the palpebral fissure; then clean the *infra-orbital head* of the quadratus labii superioris, a flat and fairly wide muscle which springs from the lower margin of the orbit, under cover of the orbicularis oculi, and descends to the upper lip, where it blends with the orbicularis oris. Lateral to the infra-orbital head, the small *zygomatic head* of the quadratus labii superioris may be found. It descends from the zygomatic bone and blends with the lower part of the lateral border of the infra-orbital head. After the zygomatic head has been cleaned turn to the lower lip region and clean the *triangularis*. It springs from the mandible above the insertion of the anterior part of the platysma and passes upwards to the angle of the mouth, where it blends with the orbicularis oris. Anterior to the triangularis, and on a deeper plane, find and clean the *quadratus labii inferioris*. It springs from the mandible under cover of and anterior to the triangularis and ascends to the orbicularis oris, with which it blends. After the muscles mentioned have been defined proceed to the detailed study of their positions and attachments.

Orbicularis Oculi.—The orbicular muscle of the eyelids, on each side, consists of a thick orbital portion which covers the superficial bony boundaries of the orbit, and a thinner and paler palpebral part which lies in the eyelids.

The *orbital portion* of the muscle extends upwards to the forehead, laterally to the temporal region and downwards into the cheek. Its fibres are relatively dark and coarse. They all take origin medially from the medial part of the palpebral

ligament, the adjoining part of the frontal bone, and the frontal process of the maxilla, and they sweep laterally round the margin of the orbit in the form of a series of concentric loops. The upper fibres blend with the frontal belly of the epicranius, and the lower fibres overlap the upper parts of the muscles of the upper lip. Some of the fibres spring from the nasal part of the frontal bone and terminate in the skin of the eyebrow.

The palpebral part consists of fibres which sweep in gentle curves from the medial palpebral ligament to the lateral palpebral raphe, to both of which they are attached. Peripherally they blend with the orbital part, and they form a continuous layer of uniform thickness, except near the free margins, where, close to the bases of the eyelashes, there is a more pronounced fasciculus, termed the *ciliary bundle*. Some of the fibres of the palpebral portion pass from the deep surface of the medial palpebral ligament to the lacrimal bone; they constitute the *pars lacrimalis*, which will be described when the eyelids are dissected (see p. 29).

The orbicularis oculi is supplied by the facial nerve. It closes the eyelids and compresses them against the eyeball. The pars lacrimalis helps to force the lacrimal secretion from the lacrimal sac into the naso-lacrimal duct. Those fibres of the orbital part of the muscle which spring from the nasal process of the frontal bone and terminate in the skin of the eyebrow pull the eyebrow towards the median plane, and throw the skin of the central part of the forehead into vertical folds; they were at one time described as a separate muscle which was called the *corrugator supercilii*.

Musculus Epicranius (O.T. **Occipito-Frontalis**).—The epicranius is a quadricipital muscle possessing two occipital heads, the occipitales muscles, and two frontal heads, the frontales muscles; they are all inserted into an intermediate aponeurosis, the *galea aponeurotica* (O.T. *epicranial aponeurosis*), which extends from the frontal to the occipital region (p. 50). The lower part of each frontal head blends with the orbicularis oculi, and from its medial border a small muscular bundle, known as the *musculus procerus* (O.T. *pyramidalis nasi*), descends to the dorsum of the nose. At present only the frontalis and the procerus have been displayed (Fig. 2).

The **Frontalis** becomes apparent immediately above the upper border of the orbicularis oculi. As it is cleaned care

should be taken to avoid injury to the branches of the supraorbital nerve which pierce it. It has little or no attachment to bone. Below, its fibres either blend with the fibres of the orbicularis oculi or they are attached to the skin of the eyebrows. Above, they terminate in the galea aponeurotica, in the region of the coronal suture. The lateral border is attached to the temporal ridge by aponeurotic fibres, and the medial border blends with its fellow of the opposite side for a short distance above the root of the nose. Above the union the medial fibres of opposite sides diverge, and below it they pass downwards over the nasal bones as the proceral muscles. The frontalis pulls the scalp forwards. It is supplied by the facial nerve.

Musculus Procerus (O.T. **Pyramidalis Nasi**).—The proceral muscles are often absent; when present, each springs from the lower and medial part of the corresponding frontalis. It descends over the nasal bone and ends on the dorsum of the nose, where some of its fibres blend with the transverse part of the nasalis and others are inserted into the skin. It is supplied by the facial nerve.

Along the lower and medial border of the orbicularis oculi will be found the muscles of the nose and the upper lip.

The proper muscles of the nose are the musculus nasalis and the musculus depressor septi, but the procerus also may be looked upon as partly a nasal muscle, and the angular head of the quadratus labii superioris has a nasal attachment.

Musculus Nasalis.—The musculus nasalis consists of two parts, the *pars transversa* (O.T. *compressor naris*) and the *pars alaris* (O.T. *dilator naris*). The pars transversa springs from the root of the frontal process of the maxilla, passes across the cartilaginous part of the nose, above the ala, and ends in an aponeurosis which connects it with its fellow of the opposite side. The pars alaris springs from the maxilla, at the side of the lower part of the anterior nasal aperture, and it terminates in the posterior part of the ala and the mobile part of the septum of the nose. The nasalis is partly concealed by the angular head of the quadratus labii superioris.

The transverse part, acting with its fellow of the opposite side, depresses the dorsum of the nose and compresses its sides. The pars alaris dilates the nostril of the same side. Both parts are supplied by the facial nerve.

Musculus Depressor Septi Nasi.—The depressor of the

nasal septum is frequently difficult to display. It springs from the superficial fibres of the upper part of the orbicularis oris, and is inserted into the anterior part of the septum of the nose. It depresses the septum and reduces the antero-posterior diameter of the anterior nasal aperture. The name indicates the action of the muscle, which is supplied by the facial nerve.

The Muscles of the Mouth and Cheeks.—The muscles of this group form two layers, a superficial and a deep. Those of the superficial group are the orbicularis oris, quadratus labii superioris, zygomaticus, triangularis, risorius, quadratus labii inferioris; those of the deeper group are the buccinator, caninus, incisivus superior and inferior, and the mentalis. All, with the exception of the orbicularis oris, are bilateral. Only the members of the superficial group are at present displayed; the deeper muscles will be dissected after the superficial vessels and nerves have been cleaned and studied.

Orbicularis Oris.—The orbicularis oris is the sphincter muscle of the oral aperture. It lies in the substance of the lips, and consists of a deeper layer of fibres which are arranged in concentric ellipsoidal rings, and a series of superficial fibres into which all the other muscles of the lips and cheeks converge. The details of its formation cannot be understood until the attachments of the other muscles have been studied (see p. 21). It is supplied by the facial nerve.

Musculus Quadratus Labii Superioris.—The quadratus labii superioris possesses three heads—a zygomatic, an infra-orbital, and an angular.

The *zygomatic head* (O.T. *zygomaticus minor*) springs from the anterior part of the facial surface of the zygomatic bone, under cover of the lower lateral part of the orbicularis oculi. It runs downwards and forwards, and either joins the infra-orbital head or is inserted into the lateral part of the upper portion of the orbicularis oris and into the adjacent part of the skin of the upper lip.

The infra-orbital head (O.T. *levator labii superioris proprius*) arises from the whole length of the infra-orbital border, under cover of the orbicularis oculi. It is inserted into the upper lateral part of the orbicularis oris and the skin of the upper lip (Fig. 2).

The *angular head* (O.T. *levator labii superioris alæque nasi*) springs from the frontal process of the maxilla. It

broadens as it descends, and it is inserted into the ala of the nose and into the upper part of the orbicularis oris.

The quadratus labii superioris raises the upper lip, and its

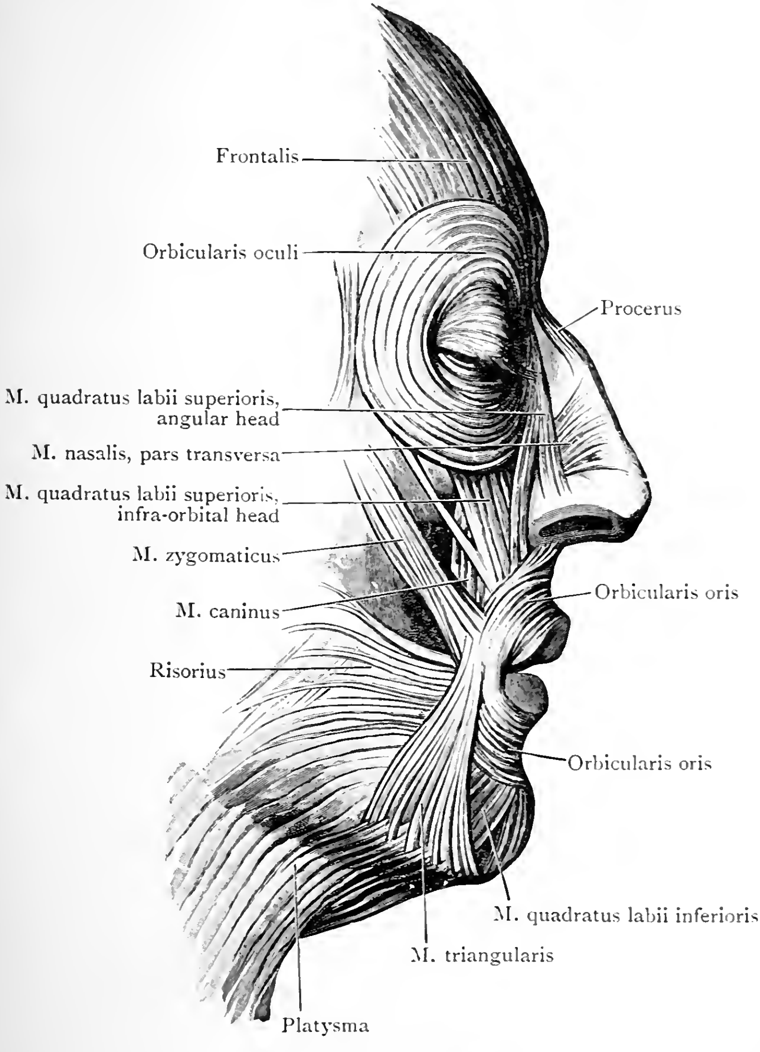

FIG. 2.—The Facial Muscles.

angular head elevates the ala of the nose. It is supplied by the facial nerve.

Musculus Zygomaticus.—The zygomaticus (O.T. zygomaticus major) is a comparatively long, slender muscular band which springs from the facial surface of the zygomatic bone, under cover of the lower lateral fibres of the orbicularis

oculi and to the lateral side of the zygomatic head of the quadratus labii superioris. Its fibres pass downwards and medially to the angle of the mouth, where some blend with the orbicularis oris and others are inserted into the skin. It pulls the angle of the mouth upwards and backwards. It is supplied by the facial nerve.

The Risorius.—When well developed the risorius muscle consists partly of some of the uppermost fibres of the platysma muscle of the neck, which bend forwards and medially to the angle of the mouth, and partly of additional fibres which spring from the fascia over the masseter muscle and the parotid gland. Both groups of fibres blend with the fibres of the orbicularis oris at the angle of the mouth. The risorius depresses the angle of the mouth and draws it backwards. It is supplied by the facial nerve.

Musculus Triangularis.—The triangularis (O.T. depressor anguli oris) springs from the oblique line on the lateral surface of the body of the mandible. Its fibres converge as they pass forwards and upwards, and, at the angle of the mouth, they blend with the orbicularis oris, in which some of them curve past the angle and terminate in the substance of the upper lip (Figs. 2, 3). It depresses the angle of the mouth, and is supplied by the facial nerve.

Musculus Quadratus Labii Inferioris (O.T. **Depressor Labii Inferioris**).—The quadrate muscle of the lower lip springs from the lower part of the superficial surface of the mandible, between the mental tubercle and the mental foramen, its posterior border being overlapped by the triangularis. The fibres pass upwards and medially, some to blend with the orbicularis oris and others to gain attachment to the skin of the lower lip. It depresses the lower lip, and is supplied by the facial nerve.

Platysma.—Only the upper part of the broad, flat, quadrangular subcutaneous muscle of the neck is at present visible. The posterior fibres ascend over the lower border of the ramus and the posterior part of the lower border of the body of the mandible, and they have already been seen taking part in the formation of the risorius. The anterior fibres gain direct insertion into the anterior part of the lower border of the body of the mandible. The latter attachment is the only bony attachment which the muscle possesses, all its other attachments being either to fascia or to skin.

It helps to depress the mandible and is supplied by the facial nerve.

Dissection.—Cut through the posterior half of the platysma along the lower border of the mandible; detach the risorius from the fascia on the masseter; then turn the risorius and the detached part of the platysma towards the angle of the mouth. Whilst doing that be careful to avoid injuring the branches of the vessels and nerves of the face (Figs. 4, 5, 15).

As soon as the platysma and the risorius are reflected search below the level of the ear for branches of the great auricular

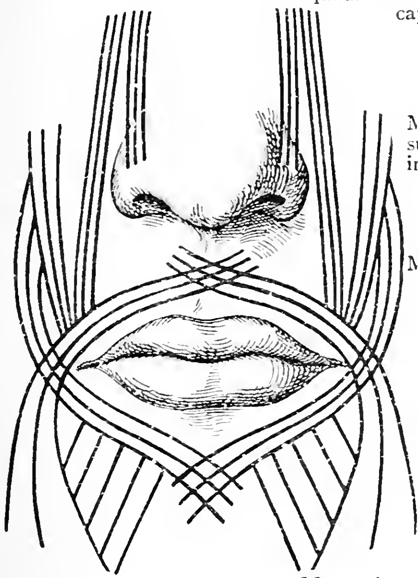

FIG. 3.—Diagram of the Orbicularis Oris Muscle.
The fibres which enter it from the buccinator are not represented.

nerve which ascend over the lower part of the parotid gland. Some of them pierce the parotid and terminate in its substance, others end in the skin of the masseteric region.

Find the anterior facial vein and the external maxillary artery at the lower and anterior angle of the masseter, as they cross the lower border of the mandible. Clean them at that point, but do not trace them towards their terminations at present.

At the posterior border of the mandible note the deep fascia over the superficial surface of the parotid gland; it is called the parotid fascia. It ascends from the fascia of the neck, and is attached above to the zygomatic arch. Note also that at the anterior border of the parotid the parotid fascia blends with the fascia on the superficial surface of the masseter muscle. Cut through the fascia covering the parotid gland immediately anterior to the ear, extending the incision from the zygoma above to the angle of the mandible below; then

raise the fascia from the gland, dissecting carefully forwards, upwards, and downwards. As the extremities and the anterior border of the gland are approached, look carefully for nerves and vessels which emerge from beneath them, and also for the duct of the gland, which appears from under cover of the anterior border about a finger's breadth below the zygoma. The duct has thick walls, is of considerable size, and is easily recognised. It runs forwards across the masseter and turns round the anterior border of the muscle, bending at right angles to its original course. It pierces, in turn, the fascia covering the buccinator muscle, the buccinator muscle itself and the mucous membrane of the mouth ; and it opens into the vestibule of the mouth, on a small papilla, opposite the second molar tooth of the maxilla. Above the duct and below the zygomatic arch find—(1) the accessory parotid, a small detached part of the parotid which lies a short distance in front of the anterior border of the main mass of the gland ; (2) the transverse facial vessels ; and (3) the zygomatic branches of the facial nerve. Below the duct find the buccal and the mandibular branches of the facial nerve. At the upper end of the parotid seek for the superficial temporal vessels. Posterior to them lies the auriculo-temporal branch of the third division of the trigeminal nerve, and anterior to them, the temporal branches of the facial nerve. From the lower extremity of the gland emerge—(1) the cervical branch of the facial nerve, (2) the posterior facial vein (O.T. anterior division of the temporo-maxillary vein), and (3) a tributary of the external jugular vein (Fig. 15).

Follow the temporal branch of the facial nerve upwards and forwards to the frontal belly of the epicranius and the upper part of the orbicularis oculi. As the temporal branch is cleaned the anterior part of the strong *temporal fascia* will be exposed. It is attached to the upper border of the zygomatic arch, the posterior border of the zygomatic bone, and the temporal line on the frontal bone. Springing from it, above the posterior part of the zygoma, is the *anterior muscle of the auricle*, and at a higher level the *superior muscle of the auricle*. Attempt to define both the muscles and the branches which pass to them from the temporal division of the facial nerve. A short distance behind a prominent tubercle, which can be felt on the posterior border of the zygomatic bone, the zygomatico-temporal branch of the maxillary division of the trigeminal nerve pierces the temporal fascia and communicates with the temporal branch of the facial nerve. An attempt should be made to secure the zygomatico-temporal nerve and to define the connection.

Further dissection is required before the zygomatic buccal and mandibular branches of the facial nerve can be traced to their terminations. As the dissection proceeds the deeper muscles of the face, branches of the trigeminal nerve and the internal maxillary artery will be exposed, whilst at the same time the externally maxillary artery and its branches and the anterior facial vein and its tributaries must be cleaned.

Follow the upper zygomatic branches of the facial nerve forwards to their termination in the lateral part of the orbicularis oculi, then reflect that muscle towards the median plane and under cover of it, emerging from the zygomatic bone, find the *zygomatico-facial branch* of the maxillary division of

the trigeminal nerve. It communicates with one of the zygomatic twigs of the facial nerve. Next follow the lower zygomatic branches of the facial nerve forwards to the zygomaticus muscle, and note that one of the twigs supplies it ; then detach the zygomaticus from its origin, turn it down to the angle of the mouth. When that has been done detach the zygomatic and infra-orbital parts of the quadratus labii superioris from their origins and turn them downwards. Now follow the anterior facial vein and the external maxillary artery forwards and upwards to the nose, and secure the branches of the artery. Some of the smaller branches pass backwards, but the main branches, the *inferior* and *superior labial*, pass forwards into the lower and upper lips respectively, where they lie deep to the orbicularis oris against the mucous membrane. Beyond the angle of the mouth the *lateral nasal branch* arises, and the continuation of the external maxillary artery beyond that branch is called the *angular artery*.

After the external maxillary artery and its branches have been cleaned follow the lower zygomatic branches of the facial nerve forwards through the fat exposed by the reflection of the zygomaticus and the quadratus labii superioris, and secure their connections with the terminal branches of the infra-orbital branch of the maxillary division of the trigeminal nerve, which issues through the infra-orbital foramen accompanied by the infra-orbital branch of the internal maxillary artery. The interlacement of the zygomatic branches of the facial nerve with the infra-orbital nerve constitutes the *infra-orbital plexus*. From the infra-orbital plexus branches ascend to the lower eyelid, other branches descend to the upper lip, and still others pass medially to the nose. After the branches of the infra-orbital plexus have been displayed clean the buccal branch of the facial nerve. Follow it through the pad of fat called the *suctorial pad* which lies on the buccinator muscle. Secure, if possible, its junction with the buccinator branch of the mandibular division of the trigeminal nerve, which issues from under cover of the middle of the anterior border of the masseter muscle, and follow its branches of supply to the buccinator muscle. It may be necessary to cut through the anterior border of the masseter to secure the buccinator branch of the mandibular nerve. Next detach the triangularis from the angle of the mouth and turn it downwards to its insertion, secure the twig it receives from the mandibular branch of the facial nerve, and display the union of that branch with the mental branch of the alveolar division of the trigeminal nerve, which issues through the mental foramen, under cover of the triangularis and below the second lower premolar tooth. Secure also a twig from the mandibular branch of the facial nerve which supplies the quadratus labii inferioris. Accompanying the mandibular nerve deep to the triangularis there is, usually, a definite branch of the external maxillary artery which used to be called the inferior labial. Finally, reflect the posterior part of the platysma below the mandible to display the cervical branch of the facial nerve, which issues from the lower part of the parotid gland to supply the platysma and to communicate with the upper branch of a cutaneous nerve called the nervus cutaneus colli. Do not follow it to its termination at present

(see p. 122). After the various structures mentioned have been cleaned proceed to the study of the anterior facial vein, the external maxillary artery, and the terminal branches of the facial nerve.

Vena Facialis Anterior (O.T. **Facial**).—The anterior facial vein is a less tortuous vessel than the external maxillary artery, to which it corresponds; and it lies posterior to the artery, and on a slightly more superficial plane (Fig. 15). It commences as the *angular vein*, which is formed at the medial commissure of the eyelids, by the union of the frontal and supra-orbital veins, which descend from the forehead. It passes downwards and backwards, in a comparatively straight line, to the anterior inferior angle of the masseter, which it crosses immediately behind the external maxillary artery; then it pierces the deep fascia of the neck, and enters the submaxillary triangle. In the upper part of the face it lies on the quadratus labii superioris; then it is situated between the zygomaticus and the risorius superficially and the buccinator deeply; and as it crosses the anterior angle of the masseter it is covered with the skin, superficial fascia, and the platysma.

Tributaries.—In addition to the frontal and supra-orbital veins, it receives external nasal, palpebral, superior labial, inferior labial, masseteric and superficial parotid tributaries. As it crosses the buccinator muscle it is joined by the *deep facial vein*, which connects it with the pterygoid plexus of veins in the infra-temporal region.

Arteria Maxillaris Externa (O.T. **Facial**).—The external maxillary artery is a tortuous vessel which enters the face at the lower and anterior angle of the masseter, after turning round the lower border of the mandible and piercing the deep fascia of the neck. From that point it runs forwards and upwards to the angle of the mouth, where it assumes a more vertical direction, and becomes the angular artery, which ascends, in the substance of the angular head of the quadratus labii superioris, to the medial commissure of the eyelids. Immediately after its entrance into the face it is comparatively superficial, being covered by skin, superficial fascia, and platysma, and it is easily compressed against the bone. More anteriorly it lies between the zygomaticus superficially and the buccinator deeply, then between the quadratus labii superioris and the caninus, which springs from the maxilla below the infra-orbital foramen. Its

terminal part is usually embedded in the substance of the quadratus labii superioris (Figs. 4, 15).

Branches.—The branches of the external maxillary artery form two groups, a posterior and an anterior. The branches

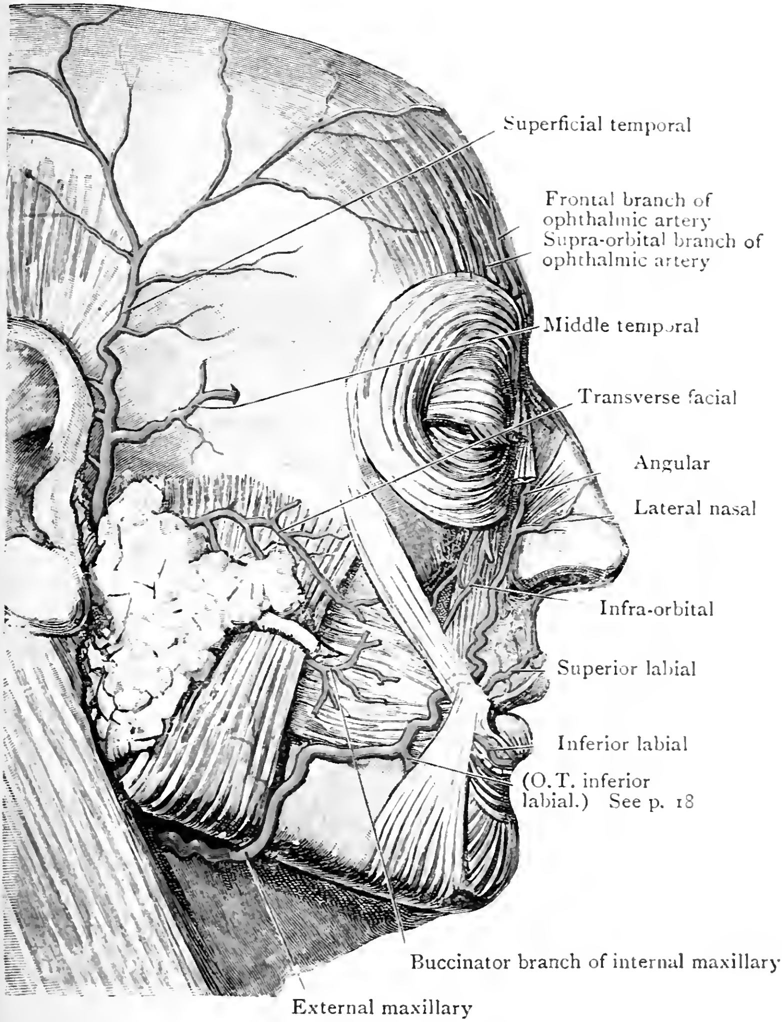

FIG. 4.—Arteries of the Face.

of the posterior group pass backwards and are of small size. They are distributed to the masseteric, buccal, and malar regions, where they anastomose with the transverse facial, the buccinator, and the infra-orbital arteries.

The branches of the anterior group, which run forwards,

receive special names: they are the inferior labial, the superior labial, the lateral nasal, and the angular continuation.

The *inferior labial* (O.T. *inferior coronary*) arises below the level of the angle of the mouth and passes towards the median plane, under cover of the triangularis, the quadratus labii inferioris, and the orbicularis oris. In the substance of the lip it lies immediately adjacent to the mucous membrane, and it anastomoses, in the median plane, with its fellow of the opposite side.

The *superior labial* arises about the level of the angle of the mouth and runs medially in the upper lip, between the orbicularis oris and the mucous membrane. Before it anastomoses with its fellow of the opposite side, it gives off a branch, *the septal artery of the nose*, which passes upwards and ramifies on the lower and anterior part of the nasal septum, where it anastomoses with the septal branch of the spheno-palatine artery.

The *lateral nasal branch* springs from the external maxillary above the angle of the mouth. It ramifies on the side of the nose and anastomoses, in the median plane, with its fellow of the opposite side.

The *angular artery* is the continuation of the external maxillary beyond the point of origin of the lateral nasal branch. It runs upwards in the substance of the angular head of the quadratus labii superioris, and it terminates, at the medial commissure of the eye, by anastomosing with the dorsal nasal branch of the ophthalmic artery.

In addition to the branches already noted, a very definite branch is usually given off from the anterior aspect of the external maxillary artery immediately after it crosses the lower border of the mandible. This branch (O.T. inferior labial) runs towards the median plane under cover of the triangularis and the quadratus labii inferioris, and it anastomoses not only with the inferior labial (O.T. inferior coronary) above, and its fellow of the opposite side in the median plane, but also with the mental branch of the inferior alveolar artery.

The Terminal Branches of the Facial Nerve.—The dissector should note that there are five terminal branches, or groups of branches, of the facial nerve: (1) temporal; (2) zygomatic; (3) buccal; (4) mandibular; (5) cervical. They all emerge from under cover of the parotid gland, the temporal branches at its upper end, the cervical at its lower

end, and the remaining three groups of branches at its anterior border (Fig. 5).

The *temporal branches* of the facial nerve cross the zygomatic arch and pass upwards and forwards towards the forehead; they supply twigs to the anterior and superior muscles of the auricle, to the upper fibres of the orbicularis

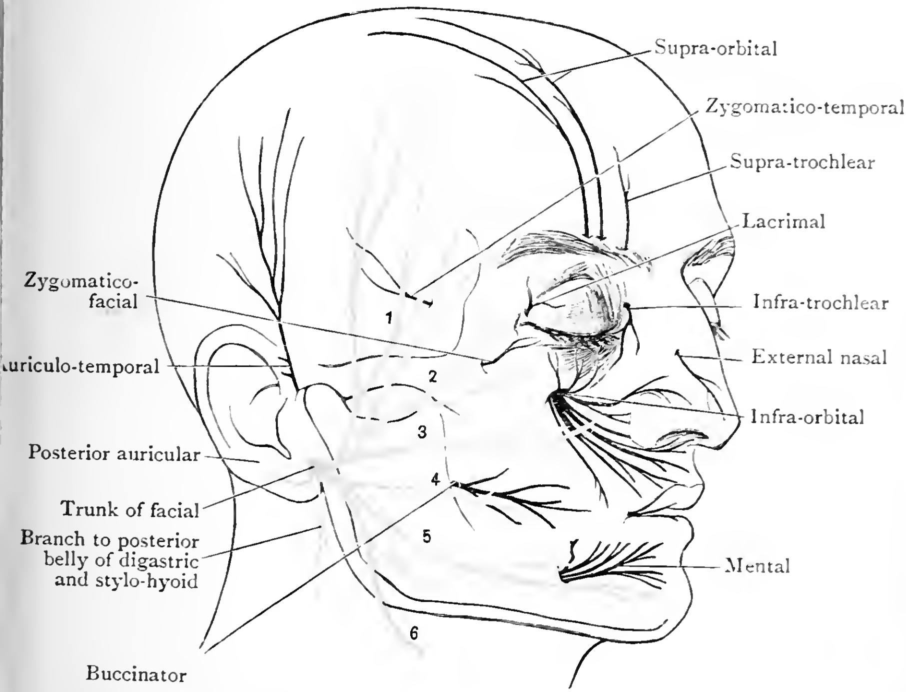

FIG. 5.—Nerves of the Face. The facial nerve is depicted in green, the sensory branches of the trigeminal in black.

1. Temporal branches.
2 and 3. Zygomatic branches.
4. Buccal branch.
5. Mandibular branch.
6. Cervical branch.

oculi and to the frontal belly of the epicranius. One of the branches communicates with the zygomatico-temporal branch of the trigeminal nerve, which pierces the temporal fascia behind the zygomatic bone.

The upper filaments of the *zygomatic branches* run forwards across the zygomatic bone, and terminate, in both the upper and the lower eyelid, in the fibres of the orbicularis oculi. If the branches are carefully traced, one of them will be found to communicate with the zygomatico-facial branch of the second or maxillary division of the trigeminal nerve.

That small nerve pierces the zygomatic bone a short distance below the lateral border of the orbit.

The lower filaments are larger. They run forwards along the lower border of the zygomatic arch, under cover of the musculus zygomaticus and the infra-orbital part of the quadratus labii superioris, and deep to the latter they communicate with the infra-orbital branch of the maxillary division of the trigeminal nerve, forming with it the *infra-orbital plexus.*

The *buccal branch or branches* run towards the angle of the mouth. At the anterior border of the masseter they communicate, around the anterior facial vein, with the buccinator branch (O.T. long buccal) of the third division of the trigeminal, and they supply the buccinator and the orbicularis oris.

The *mandibular branch or branches* run forwards along the mandible to be distributed to the muscles of the lower lip. They pass deep to the triangularis, and they communicate, under cover of it, with the mental branch of the inferior alveolar (O.T. dental) nerve.

The *cervical branch* after its exit from the lower end of the parotid gland runs downwards and forwards to supply the platysma and to communicate with the nervus cutaneus colli, but since neither the terminal branches nor the communication can be seen at present they will be displayed at a later stage of dissection (see p. 122).

Dissection.—After the branches of the facial nerve, the external maxillary artery and the anterior facial vein have been studied, the dissection of the deeper muscles and the deeper vessels and nerves must be proceeded with; but the supra-orbital and supra-trochlear nerves, and the supra-orbital vessels, may be left till the scalp is dissected (p. 47).

First clean the *caninus muscle* which lies deep to the infra-orbital plexus and descends to the angle of the mouth, where it blends with the orbicularis oris. Then clean the remains of the fat from the surface of the *buccinator*, and as the fat is being removed note the small *molar glands* which lie in it and the strong deep bucco-pharyngeal fascia which covers the muscle. The ducts of the molar glands pierce the bucco-pharyngeal fascia and the buccinator and open into the vestibule of the mouth. Clean away the bucco-pharyngeal fascia and define the attachments of the buccinator to the maxilla and the mandible, and trace its fibres forwards to the angle of the mouth, where they blend with the orbicularis oris.

Musculus Caninus (O.T. **Levator Anguli Oris**).—The caninus is concealed by the lower part of the orbicularis

oculi, the quadratus labii superioris, and the zygomaticus, and it is crossed superficially, near the angle of the mouth, by the external maxillary artery. When the structures superficial to it are turned aside, the muscle will be found springing from the canine fossa below the infra-orbital foramen. It passes downwards to the angle of the mouth, where it blends with the orbicularis oris, some of its fibres passing into the lower lip (Fig. 3). It is an elevator of the angle of the mouth and is supplied by the facial nerve.

M. Buccinator.—The buccinator muscle occupies the interval between the maxilla and the mandible and forms a most important part of the substance of the cheek. Above, it springs from the alveolar border of the maxilla, in the region of the molar teeth. Below, it arises from the

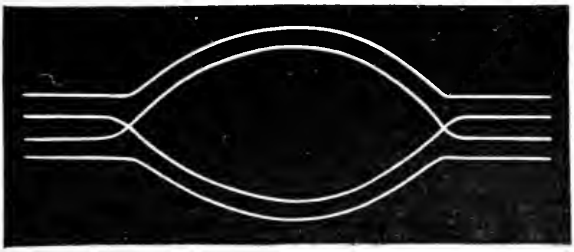

FIG. 6.—Arrangement of the Fibres of the Buccinator Muscles at the Angles of the Mouth.

alveolar border of the mandible, also in the region of the molar teeth, and, posteriorly, it is attached to the pterygo-mandibular raphe, which forms a bond of union between the buccinator and the superior constrictor of the pharynx. The last-mentioned attachment will be seen to better advantage when the wall of the pharynx is studied (p. 286). Anteriorly, the fibres of the buccinator converge towards the angle of the mouth, where they blend with the orbicularis oris, of which they form a large part. The manner in which the fibres enter the orbicularis must be carefully noted. The upper and lower fibres pass directly to the corresponding lips; the middle fibres, on the other hand, decussate at the angle of the mouth, so that the lower fibres of the series enter the upper lip, whilst the higher fasciculi reach the lower lip (Fig. 3).

The buccinator muscle is not classified as a muscle of mastication, but it is used during mastication to prevent food

accumulating between the cheeks and the teeth, the contractions of the muscle forcing the food back, between the teeth, into the cavity of the mouth proper. It is also used for blowing and whistling. It is supplied by the facial nerve.

The Molar Glands.—The pad of fat which covered the buccinator posteriorly, and which was removed, as the buccal branch of the mandibular nerve was cleaned, is known as the corpus adiposum buccæ, or *suctorial pad.* Its removal exposed the bucco-pharyngeal fascia and a number of small glands, called the *molar salivary glands.* The ducts of the molar glands pierce the buccinator and open into the vestibule of the mouth. One or two *buccal lymph glands* also are sometimes found resting on the superficial surface of the buccinator.

Dissection.—After the dissection of the buccinator and the molar glands is completed, remove the stitches from the lips; evert the lips and dissect the mucous membrane from the deep surfaces, in order to expose the muscular slips which attach the orbicularis oris to the alveolar margins of the maxilla and the mandible, and to display the mentalis muscle. As the lips are everted the dissector should note that a fold of mucous membrane, the *frenulum labii,* passes from each lip to the adjacent gum in the median plane; and as the mucous membrane is removed a number of small *labial salivary glands,* which lie in the submucous tissue, will be seen. They are readily felt in the living subject when the tip of the tongue is pressed against the inner surfaces of the lips.

Musculi Incisivi Labii Superioris et Inferioris.—The incisive muscles of the upper and lower lips are four small muscular bundles, two upper and two lower, which attach the deeper part of the orbicularis oris to the alveolar margins of the maxillæ and mandible in the regions of the upper and lower lateral incisor teeth.

Musculus Mentalis.—When the incisive muscles of the mandible are detached from the bone and the lower lip is further everted, a distinct muscular bundle will be found on each side, springing from the outer surface of the socket of the canine tooth, under cover of the quadratus labii inferioris. The two bundles converge and blend together, between the medial borders of the musculi quadrati labii inferioris, to form a single bundle which is inserted into the skin of the chin. It is an elevator of the skin of the chin. It is supplied by the facial nerve.

Nervus Buccinatorius (O.T. **Long Buccal**).—The buccinator

nerve is a branch of the mandibular division of the trigeminal nerve. It passes forwards into the cheek from under cover of the ramus of the mandible. It is a sensory nerve, and it supplies branches to the skin on the outer surface, and the mucous membrane on the inner surface, of the buccinator muscle. Its communications with the buccal branch of the facial nerve has already been referred to (see p. 20).

Palpebræ.—In the eyelids the following strata will be exposed as the dissection is carried from the surface towards the conjunctiva.

Upper Lid.	Lower Lid.
1. Integument.	1. Integument.
2. Palpebral part of the orbicularis oculi.	2. Palpebral part of the orbicularis oculi.
3. The tarsus, the palpebral fascia, and the expanded tendon of the levator palpebræ superioris.	3. The tarsus and the palpebral fascia.
4. Conjunctiva.	4. Conjunctiva.

In addition to the structures enumerated in the above list, two ligamentous bands, named the medial palpebral ligament (O.T. internal tarsal ligament) and the lateral palpebral raphe (O.T. external tarsal ligament), will be noticed. They attach the tarsi to the medial and lateral margins of the orbit.

Integument and Orbicularis Oculi.—Both the skin and the orbicularis oculi have been examined already, and the skin has been reflected.

> ***Dissection.***—Separate the palpebral part of the orbicularis oculi from the remainder by a circular incision; turn the palpebral part towards the rima palpebrarum, and take care, whilst raising the muscle fibres, to preserve the palpebral vessels and nerves, and at the same time to avoid injury to the palpebral fascia. As the dissection is completed the origin of the muscle from the medial palpebral ligament (p. 7) will be displayed.

Tarsi.—The removal of the palpebral part of the orbicularis oculi brings into view the palpebral fascia and the tarsi. They lie in the same morphological plane, and they constitute the ground-work of the eyelids (Fig. 7).

The *tarsi* are two thin plates of condensed fibrous tissue,

three lamellæ: a superior lamella, which blends with the upper part of the palpebral fascia and is attached with it to the anterior surface of the upper tarsus; an intermediate lamella, which is connected with the upper border of the upper tarsus; and an inferior lamella, which gains insertion into the upper fornix of the conjunctiva. It raises the upper eyelid by pulling on the upper tarsus, and at the same time elevates the upper fornix of the conjunctiva. It is supplied by the oculo-motor nerve.

Vessels and Nerves of the Eyelids.—At the medial commissure two arteries, the *palpebral branches* of the ophthalmic,

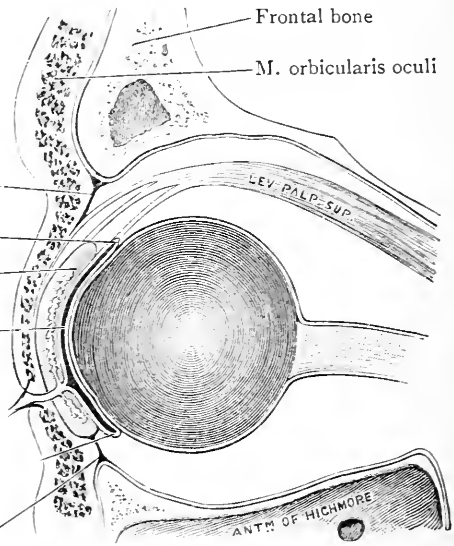

FIG. 8.—Diagram of the Structure of the Eyelids.

pierce the palpebral fascia and run laterally, one in the upper and one in the lower lid. At the lateral margin of the orbit, one or more branches of the lacrimal division of the ophthalmic pierce the palpebral fascia and anastomose with the palpebral branches of the ophthalmic. An arterial arch, *arcus tarseus*, is thus formed close to the margin of each eyelid, between the orbicularis muscle and the tarsus.

The veins run medially towards the root of the nose and open into the frontal and angular veins.

The nerves are more numerous and come from a number of different sources. The motor filaments for the various parts of the orbicularis oculi are derived from the temporal

and zygomatic branches of the facial nerve. They enter from the lateral margins. The sensory twigs for the upper lid come from the lacrimal, supra-orbital, supra-trochlear, and infra-trochlear branches of the first or ophthalmic division of the trigeminal nerve; and the lower lid is supplied by the infra-orbital branch of the maxillary division of the fifth cerebral nerve. The lacrimal nerve will be found piercing the palpebral fascia near the lateral part of the upper border of the orbit; the supra-orbital lies in the supra-orbital notch at the junction of the lateral two-thirds with the medial third of the upper border; and the supra- and infra-trochlear pierce the palpebral fascia at the medial end of the upper border. The branches of the infra-orbital nerve pass to the lower lid in the palpebral branches of the infra-orbital plexus (p. 20).

Apparatus Lacrimalis.—The following structures are included under this head: (1) the lacrimal gland and its ducts; (2) the conjunctival sac; (3) the puncta lacrimalia; (4) the lacrimal ducts; (5) the lacrimal sac; (6) the naso-lacrimal duct; (7) the lacrimal part of the orbicularis oculi.

Glandula Lacrimalis. — The lacrimal gland lies in the upper and lateral part of the orbital cavity, under cover of the zygomatic process of the frontal bone. It can be exposed by cutting through the palpebral fascia at the upper and lateral angle of the orbit, and it will be found that the anterior part of the gland projects slightly beyond the orbital margin and rests upon the conjunctiva, as the latter is reflected from the lateral part of the upper lid on to the eyeball. If the anterior border of the gland is raised and the point of the knife is carried carefully up and down in the fascia under it, several exceedingly fine ducts will be found passing from the gland into the lateral part of the upper fornix of the conjunctiva (Fig. 9).

The ducts vary in number, and the secretion they convey, which constitutes the tears, is carried, by the involuntary movements of the upper eyelid, over the exposed surface of the eyeball and is directed towards the medial commissure; there it passes through the puncta lacrimalia into the lacrimal ducts, and is carried by them to the lacrimal sac, whence it passes by the naso-lacrimal duct into the inferior meatus of the nose. Under ordinary circumstances, the amount of lacrimal secretion is sufficient merely for lubrication, and practically the whole of it is evaporated from the

surface of the eyeball; consequently, when the lacrimal ducts and the lacrimal sac are extirpated, a proceeding which is necessary under certain circumstances, the patient suffers little or no inconvenience from the overflow of tears, so long as the secretion is not excessive. If the amount of secretion

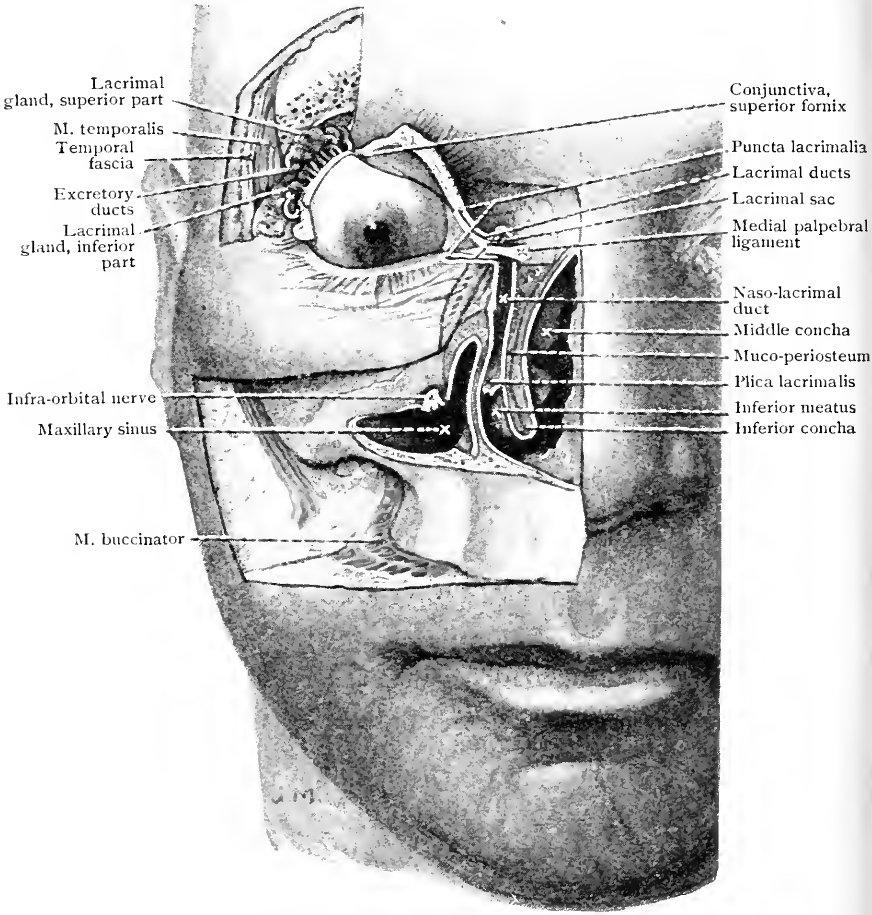

FIG. 9.—Dissection of Lacrimal Apparatus.

is greater than can be removed by evaporation, the excess, under ordinary circumstances, passes through the puncta into the ducts and thence through the lacrimal sac and naso-lacrimal duct to the inferior meatus of the nose. If the secretion becomes so abundant that it cannot be removed by evaporation and drainage, part flows through the rima as tears.

The Conjunctival Sac.—The cavity of the conjunctival sac is the potential space between the eyelids and the eyeball. It opens externally through the rima, and communicates with the lacrimal sac through the puncta and the lacrimal ducts.

Puncta Lacrimalia.—It has been noted already that the punctum lacrimale of each lid lies at the lateral margin of the lacus lacrimalis (p. 4). Small probes should now be passed through the puncta into the lacrimal ducts and along the ducts into the lacrimal sac (Fig. 9).

Saccus Lacrimalis.—The lacrimal sac is the blind upper end of a canal which extends from the orbit to the inferior meatus of the nose. It is lodged in the fossa lacrimalis in the anterior part of the medial wall of the orbit. It lies posterior to the medial palpebral ligament, from which it receives a fibrous expansion, and it is covered on its lateral aspect, and on the lateral part of its posterior aspect, by the pars lacrimalis of the orbicularis oculi. The lacrimal ducts open into its antero-lateral aspect, under cover of the medial palpebral ligament; and it is continuous below with the naso-lacrimal duct. The anterior wall of the sac should be incised and a probe should be passed down the naso-lacrimal duct into the inferior meatus of the nose. Note that as the probe passes along the duct it inclines downwards, laterally and slightly backwards.

Pars Lacrimalis M. Orbicularis Oculi (O.T. *Tensor Tarsi*).—The lacrimal part of the orbicularis oculi springs from the posterior aspect of the lateral part of the medial palpebral ligament and passes backwards and medially, round the lateral part of the lacrimal sac, to the crista lacrimalis of the lacrimal bone, to which it is attached. When it contracts it compresses the lacrimal sac, and so tends to facilitate the flow of the lacrimal secretion into the nose.

Ductus Naso-Lacrimalis.—The naso-lacrimal duct will be seen at a later period of the dissection. It lies in a bony canal in the lateral wall of the nose, and extends from the lacrimal sac to the upper and anterior part of the inferior meatus. It is about 12.5 mm. (half an inch) long, and its walls are composed of muco-periosteum. At the medial side of its lower end is a fold of mucous membrane, the *plica lacrimalis*, which serves as a flap valve (Fig. 9).

Dissection.—**The dissection of the face should be completed by an examination of the nasal cartilages and the external nasal**

branch of the ophthalmic division of the trigeminal nerve. The nerve will be found emerging between the lower border of the nasal bone and the lateral cartilage of the nose. After its emergence it descends to the tip of the nose, supplying filaments to the skin. After it has been displayed, strip off the nasalis muscle and the remains of the integument and examine the cartilaginous part of the nose.

Cartilagines Nasi.—In addition to the septal cartilage, which will be more appropriately studied in the dissection of the nasal cavities, two cartilaginous plates will be found upon each side. They are :—

1. The lateral cartilage.
2. The cartilage of the ala.

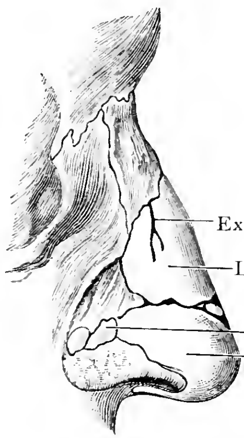

FIG. 10.—Cartilages of the Nose.

The *lateral cartilage* is triangular in form. Its posterior margin is attached to the lower border of the nasal bone and the upper part of the sharp margin of the nasal notch of the maxilla. The upper part of the medial border is continuous with the corresponding cartilage of the opposite side, and also with the subjacent anterior border of the septal cartilage of the nose; but the lower parts of the medial borders of the lateral cartilages are separated by a small interval in which the margin of the nasal septal cartilage is seen. The inferior border of the lateral cartilage is connected with the lateral part of the alar cartilage by fibrous tissue.

The *alar cartilage* is a bent plate which is folded round the anterior part of the nasal orifice. The *lateral part* is oval, and reaches neither down to the margin of the nostril,

nor posteriorly as far as the nasal notch of the maxilla. The interval between it and the bone is filled in by fibrous tissue in which one or two small islands of cartilage (cartilagines minores vel sesamoideæ) appear. *Anteriorly*, the bent part of cartilage comes into contact with its neighbour and forms the point of the nose. The *medial part* of the cartilage is a narrow strip which lies against the lower part of the septal cartilage, and projects slightly below it, so as to support the margin of the nostril upon the medial side. Its posterior extremity is turned slightly laterally.

SIDE OF THE NECK.

On the fourth day after the body is brought into the room it is placed upon its back, and the dissectors of the head and neck should examine the side of the neck and commence the dissection of the posterior triangle.

The side of the neck is bounded *below* by the clavicle, *above* by the lower border of the mandible, the mastoid portion of the temporal bone, and the superior nuchal line of the occipital bone. *Anteriorly* it extends to the median plane, and *posteriorly* to the anterior border of the trapezius muscle. It is divided into anterior and posterior parts, the *anterior* and *posterior triangles*, by the sterno-mastoid muscle. If the head is pulled over towards the opposite side, the sterno-mastoid muscle will be seen descending from the mastoid portion of the temporal bone and the superior nuchal line of the occipital bone, to the upper border of the sternal third of the clavicle and the anterior surface of the manubrium sterni.

In the lower part of the posterior region, posterior to the sterno-mastoid and above the convex middle third of the clavicle, there is a depression called the *fossa supraclavicularis major*, to distinguish it from the *fossa supraclavicularis minor*, which lies between the sternal and clavicular heads of the sterno-mastoid, above the sternal end of the clavicle. The fossa supraclavicularis major overlies the brachial plexus, the third part of the subclavian artery, and the supra-clavicular lymph glands; and the fossa supraclavicularis minor indicates the position of the lower part of the internal jugular vein.

POSTERIOR TRIANGLE.

Dissection.—To expose the boundaries and contents of the posterior triangle make the following three incisions through the skin. (1) From the back of the auricle, along the upper border of the mastoid part of the temporal bone and the superior nuchal line to the external occipital protuberance. (2) From the sternal to the acromial end of the clavicle, following the line of that bone. (3) Join the anterior extremities of 1 and 2 by an incision, passing along the back of the external acoustic meatus, and then down the middle of the sterno-mastoid muscle. Reflect the flap, thus marked out, from before backwards, and note that the skin is thicker over the upper and posterior part of the triangle than over the lower and anterior part.

When the skin is reflected the superficial fascia and the lower part of the platysma muscle will be exposed.

The *superficial fascia* in the region of the posterior triangle is comparatively thin, and embedded in its lower and anterior part is the lower and posterior part of the platysma.

M. Platysma.—The platysma is a thin sheet of muscle which commences in the superficial fascia of the infra-clavicular region, whence it ascends, across the clavicle and through the superficial fascia of the side of the neck, to the face, where its upper border has been examined already (p. 7). It covers the lower and anterior part of the posterior triangle, and the upper and posterior part of the anterior triangle; and it is supplied by the cervical branch of the facial nerve, which emerges from the lower end of the parotid gland.

Dissection.—Make an incision through the lower part of the platysma along the line of the clavicle, and turn the part above the incision upwards and forwards. Whilst making the incision and whilst reflecting the muscle, be careful not to injure the supra-clavicular cutaneous nerves and the external jugular vein, which lie directly subjacent to the platysma.

After the platysma is reflected, clean the external jugular vein, which commences at the lower end of the parotid gland, and passes downwards, inclining backwards, to the lower and anterior angle of the posterior triangle, where it pierces the deep fascia. (See pp. 34, 40, and Figs. 11 and 15.) Whilst cleaning the vein, avoid injury to the nervus cutaneus colli, which sometimes crosses superficial to the vein about the middle of its length. Secure and clean the posterior auricular vein, which descends behind the auricle and joins the external jugular a little below the level of the angle of the mandible. Next, find and clean the superficial branches of the cervical plexus as they pierce the deep fascia. They are: (1) *Descending branches*, the anterior, middle, and posterior supra-clavicular nerves. (2) A *transverse branch*, the nervus cutaneus colli (O.T. transverse cervical). (3) *Ascending branches*, the great auricular and the lesser occipital (Figs. 11, 15).

The *anterior* and *middle supra-clavicular nerves* will be found piercing the deep fascia immediately above the clavicle, the anterior at the posterior border of the sterno-mastoid and the middle above the convexity of the clavicle. They descend into the pectoral region as far as the lower border of the second rib

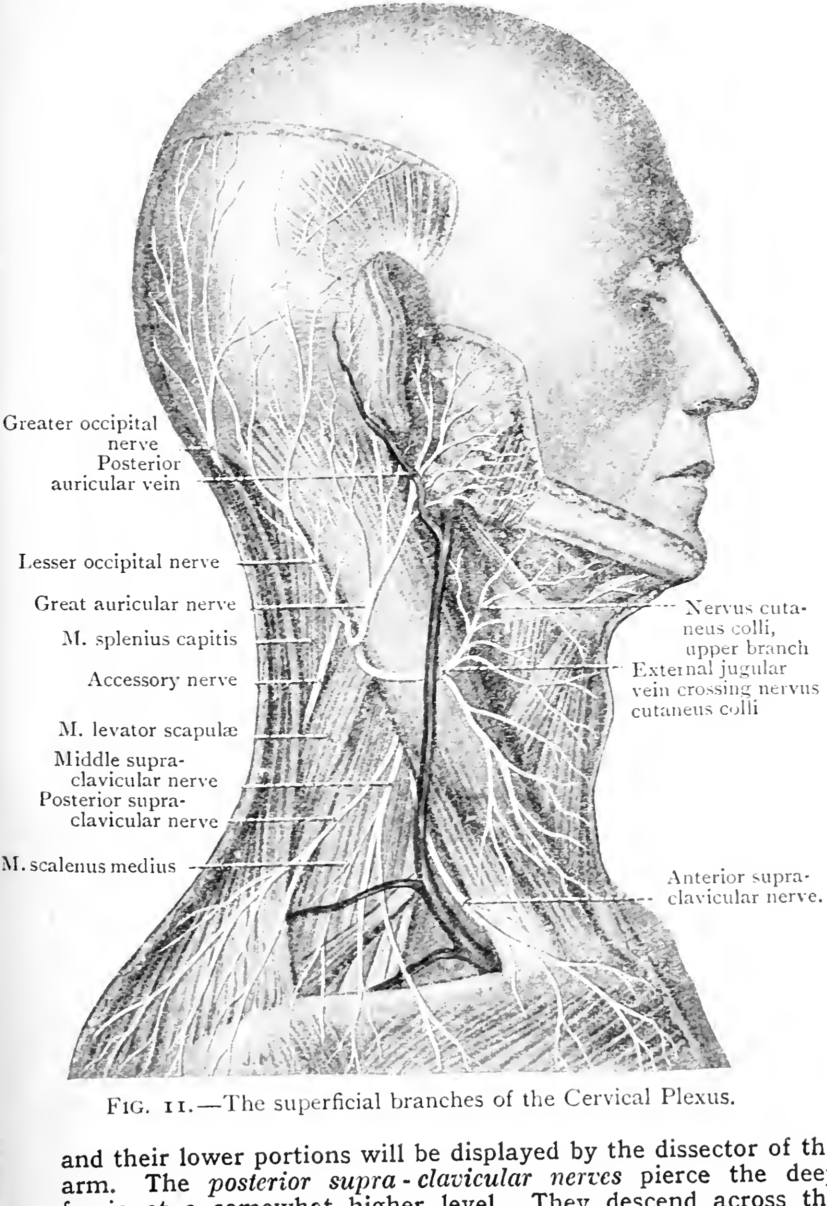

FIG. 11.—The superficial branches of the Cervical Plexus.

and their lower portions will be displayed by the dissector of the arm. The *posterior supra-clavicular nerves* pierce the deep fascia at a somewhat higher level. They descend across the lower and anterior part of the trapezius to the acromial region, and to the skin of the arm over the proximal part of the deltoid, where they will be exposed by the dissector of the arm (Fig. 11).

The *Deep Fascia.*—The deep fascia forms the superficial boundary or roof of the posterior triangle. It is attached, below, to the upper border of the middle third of the clavicle; above, to the superior nuchal line of the occipital bone; anteriorly, it is continuous with the fascia of the sterno-mastoid, and posteriorly, with the fascia of the trapezius. It is pierced by—(1) the supra-clavicular branches of the cervical plexus, (2) the external jugular vein, (3) small cutaneous branches of the transverse cervical, transverse scapular (O.T. suprascapular), and occipital arteries, and, occasionally, by the occipital artery itself. It is not a very strong layer, and it is frequently difficult to display it as a continuous sheet. Over the upper part of the triangle it forms a single layer, but below it splits into two lamellæ, a superficial and a deep. The superficial layer, which is already displayed, is attached to the upper border of the clavicle from the sterno-mastoid anteriorly to the trapezius posteriorly. It is pierced by the external jugular vein and the supraclavicular nerves.

Dissection.—Trace the supra-clavicular nerves upwards, through the deep fascia, to the posterior border of the sterno-mastoid; then, pulling them aside, cut through the superficial layer of the deep fascia immediately above the clavicle and along the posterior border of the sterno-mastoid, and turn it upwards. Introduce the handle of the scalpel behind the clavicle and note that it can be passed downwards as far as the posterior border of the lower surface of the bone. Its further progress is barred by the attachment of the second layer of the deep fascia to that border, where it blends with the posterior lamella of the costo-coracoid membrane. Pass the handle of the knife forwards deep to the sterno-mastoid, and note that, without using any great force, it can be pushed medially until it crosses the median plane; therefore, the space between the two layers of deep fascia in the lower part of the posterior triangle is continuous anteriorly with the space which lies above and posterior to the manubrium sterni, between the first and the second layers of the deep fascia of the anterior part of the neck. Laterally, that space extends as far as the coracoid process, and upwards to a short distance above the posterior belly of the omo-hyoid muscle, which lies a little above the clavicle. Take away the areolar tissue which lies between the two layers of the deep fascia, and expose a further part of the external jugular vein, and the terminal parts of the transverse cervical and the transverse scapular (suprascapular) veins, as they join the posterior border of the external jugular. Pull the lower part of the external jugular vein backwards and expose the termination of the anterior jugular vein in its anterior border. Dissect carefully behind the clavicle and find the transverse scapular (suprascapular) artery. Trace the second layer of the deep fascia upwards and note that it is continuous with the fascia which surrounds the posterior

belly of the omo-hyoid muscle ; indeed, it is the tension of the second layer of the deep fascia which holds the posterior belly of the muscle down in its position (Fig. 51).

Remove the remaining parts of the deep fascia, first from the upper, and then from the lower part of the triangle, and expose the floor and the remaining contents of the triangle.

Commence above, in the region of the junction of the upper third and the lower two-thirds of the posterior border of the sterno-mastoid, and secure the great auricular, the lesser occipital and the accessory nerves, and the nervus cutaneus colli. The great auricular is most easily found. It turns round the posterior border of the sterno-mastoid, in the region indicated, and runs upwards and forwards, parallel with and slightly above and posterior to the external jugular vein. The lesser occipital will be found hooking round the lower border of the accessory nerve a little above the great auricular ; and the nervus cutaneus colli lies a little below the great auricular.

Follow the lesser occipital and the great auricular nerves to their terminations ; but the nervus cutaneus colli must be traced only to the point where it crosses either superficial or deep to the external jugular vein. It eventually divides into upper and lower terminal branches, which will be seen when the anterior triangle is dissected.

Nervus Occipitalis Minor.—The lesser occipital is a sensory branch of the second cervical nerve. It emerges from under cover of the sterno-mastoid, and ascends for a short distance along its posterior border; then it passes to the superficial surface of the muscle, pierces the deep fascia, and divides into occipital, mastoid, and auricular branches. The occipital and mastoid branches supply the skin in the regions indicated by their names. The auricular branch is distributed to the skin of the upper third of the cranial surface of the auricle.

Nervus Auricularis Magnus.—The great auricular nerve arises from the second and third cervical nerves. After turning round the posterior border of the sterno-mastoid, it runs upwards and forwards, on the superficial surface of the sterno-mastoid, towards the angle of the mandible. It breaks up into three sets of terminal cutaneous branches—mastoid, auricular, and facial. The *mastoid branches* go to the skin of the mastoid region. The *auricular branches* supply the skin of the lower two-thirds of the cranial surface and the lower third of the lateral surface of the auricle. The *facial branches*, which have already been seen, ramify in the posterior part of the face, in the parotid and masseteric regions. Some of the filaments enter the substance of the parotid gland.

Dissection.—The accessory nerve, previously found at the junction of the upper third with the lower two-thirds of the posterior border of the sterno-mastoid, must now be traced downwards and backwards, through the triangle, to the point where it disappears under cover of the trapezius, at the junction of the upper two-thirds with the lower third of the anterior border of that muscle. As the nerve is cleaned, attempt to secure twigs from the third and fourth cervical nerves which communicate with it in the posterior triangle.

Turn next to the posterior belly of the omo-hyoid muscle, which crosses the lower part of the triangle. Note that it divides the triangle into a large upper or occipital portion, and a small lower or subclavian portion. Cut through the fascia on the surface of the muscle, parallel with the muscle fibres, and turn it upwards and downwards ; then turn the upper border of the muscle laterally and find the nerve from the ansa hypoglossi which emerges from under cover of the sterno-mastoid and enters the deep surface of the posterior belly of the omo-hyoid to supply it.

Now remove any parts of the fascial roof of the upper part of the posterior triangle which are still present, and note a number of lymph glands which lie embedded in the subjacent areolar tissue ; they are placed along the posterior border of the sterno-mastoid, superficial to the stems and branches of the cervical nerves. At the apex of the triangle look for the occipital artery, which either emerges between the adjacent borders of the trapezius and the sterno-mastoid, or pierces the trapezius a little further back.

Between the accessory nerve above and the posterior belly of the omo-hyoid below find :—(1) the upper part of the brachial plexus ; (2) its branch to the subclavius ; (3) its suprascapular branch ; (4) its dorsalis scapulæ branch ; (5) its long thoracic branch ; (6) branches from the third and fourth cervical nerves to the levator scapulæ ; (7) branches from the third and fourth cervical nerves to the trapezius, and others which communicate with the accessory nerve in the posterior triangle ; and (8) the upper and posterior part of the transverse cervical artery. Find the transverse cervical artery as it appears from under cover of the upper border of the omo-hyoid. It runs upwards and backwards. Next, secure the nerve to the subclavius, which lies under cover of the deep fascia above the omo-hyoid immediately behind the sterno-mastoid. Trace it upwards to its origin from the trunk formed by the union of the fifth and sixth cervical nerves. Clean the latter nerves and the upper part of the seventh cervical nerve, which lies immediately below them. Then find the suprascapular nerve, which springs from the lateral border of the trunk formed by the fifth and sixth nerves. It lies immediately above the anterior part of the posterior belly of the omo-hyoid, and disappears under cover of the posterior part. Turn the trunk formed by the fifth and sixth cervical nerves forwards and find, posterior to it, the upper roots of the long thoracic nerve, which spring from the fifth and sixth nerves, and are emerging through the fibres of the scalenus medius muscle. The nervus dorsalis scapulæ (O.T. nerve to the rhomboids) lies at a slightly higher level than the suprascapular nerve. It springs from the fifth cervical nerve, runs downwards and

backwards, and disappears, through the floor of the triangle, between the adjacent borders of the levator scapulæ above and the scalenus medius below. Above the dorsal scapular nerve are the branches from the third and fourth cervical nerves to the trapezius and the communications to the accessory nerve.

When the structures mentioned above have been found and cleaned, proceed to the dissection of the subclavian portion of the triangle. Find the transverse scapular artery which lies behind the clavicle, and therefore, strictly speaking, outside the limits of the triangle. Then remove the second layer of deep cervical fascia which binds the posterior belly of the omo-hyoid to the posterior border of the clavicle, and find behind it:—(1) a further part of the external jugular vein; (2) a further part of the transverse cervical artery; (3) the lower part of the nerve to the subclavius; (4) the upper portion of the third part of the subclavian artery; (5) the lowest root and the lower parts of the trunks of the brachial plexus; (6) a part of the long thoracic nerve; (7) inferior deep cervical lymph glands.

First clean the lower end of the external jugular vein and follow it behind the clavicle to its termination in the subclavian vein. Note the valves near its lower end. Next clean the transverse cervical artery and the nerve to the subclavius. Follow the nerve to the subclavius across the front of the third part of the subclavian artery; and afterwards clean the lower part of the subclavian artery and the adjacent part of the brachial plexus, which lies behind and above the artery. Note that the artery and the plexus are covered by a layer of deep cervical fascia, the backward prolongation of the prevertebral layer of fascia, which passes on to them from the lateral border of the scalenus anterior, which lies deep to the posterior border of the sterno-mastoid. The fascia is prolonged along the plexus and the artery to become continuous with the sheath of the axillary artery.

As the areolar tissue is cleared from the subclavian portion of the triangle a number of inferior deep cervical lymph glands may be noted. They receive lymph from the axillary glands, and they transmit it to the large lymph vessels at the root of the neck (Fig. 14, p. 29, Vol. I.).

After the contents of the lower part of the triangle are thoroughly cleaned, remove the remains of the fascia covering the muscles which form the floor of the triangle. Note that that fascia is continuous anteriorly, round the tips of the transverse processes of the cervical vertebræ, with the prevertebral fascia. Posteriorly, it blends with the sheaths of the deeper muscles at the back of the neck; above, it is attached to the superior nuchal line; and below, as already stated, it is prolonged into the axilla along the axillary vessels and nerves.

Boundaries and Contents of the Posterior Triangle.—The dissection of the triangle should be completed in two days. On the third day the dissector should revise his knowledge of the boundaries and the relative positions of the contents.

The triangle is bounded *anteriorly* by the posterior border of the sterno-mastoid; *posteriorly* by the anterior border of the

trapezius; *below* by the upper border of the middle third of the clavicle; and *above* by the superior nuchal line of the occipital bone, or by the meeting of the upper ends of the sterno-mastoid and the trapezius. The *roof* is formed by the deep

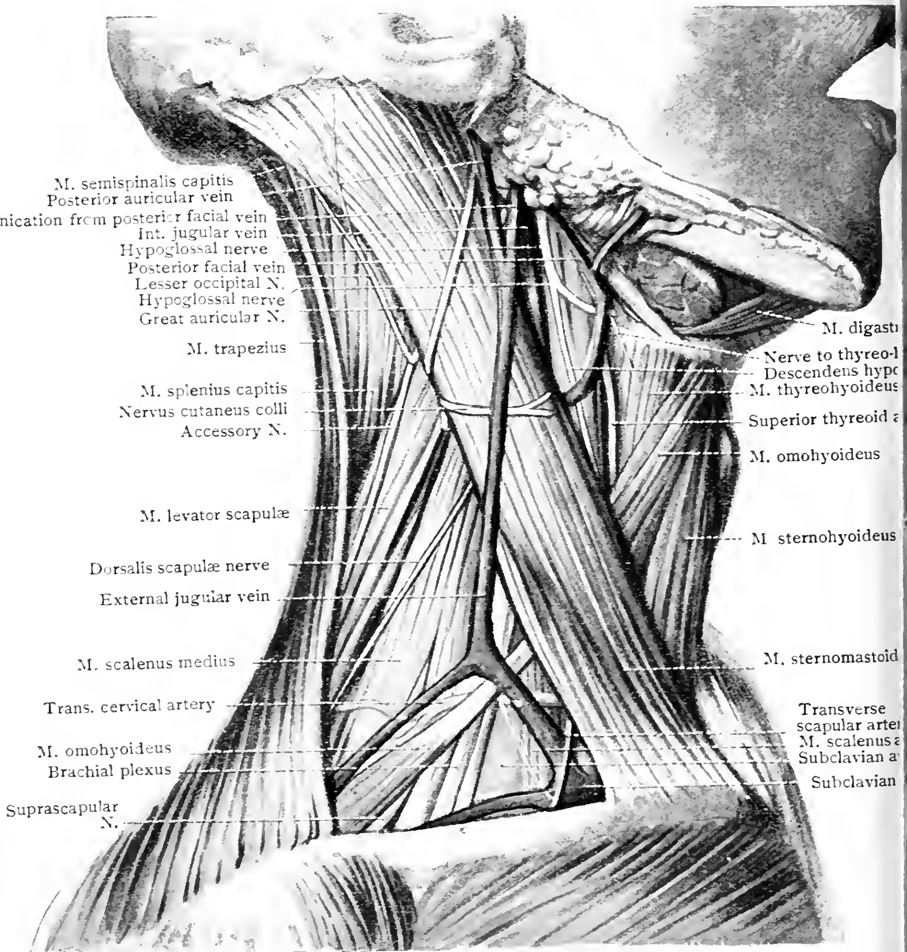

FIG. 12.—The Triangles of the Neck seen from the side. The clavicular head of the sterno-mastoid muscle was small, and therefore a considerable part of the scalenus anterior muscle is seen.

cervical fascia, which is covered by superficial fascia and skin, and in its lower and anterior part by the platysma, which is embedded in the superficial fascia. It is pierced by—(1) the external jugular vein, at the lower and anterior angle; (2) the supraclavicular nerves, a short distance above the clavicle; (3) small cutaneous branches of the transverse scapular, trans-

verse cervical, and occipital arteries; (4) lymph vessels, passing from the superficial structures to the glands in the triangle. It is frequently stated that the lesser occipital and great auricular nerves and the nervus cutaneus colli also pierce the roof. As a general rule, they turn round the posterior border of the sterno-mastoid, under cover of the fascia, and pierce the fascia which lies on the sterno-mastoid muscle.

The *floor* is formed by the splenius capitis, the levator scapulæ, the scalenus medius, and the scalenus posterior muscles, with the addition, occasionally, of a small part of the semispinalis capitis (O.T. complexus), above, and the upper serration of the serratus anterior, below; the latter appears in the area of the triangle only when the clavicle is very fully depressed. The muscles of the floor are covered with a layer of fascia which is the backward continuation of the prevertebral fascia of the anterior cervical region.

The contents of the posterior triangle are:—

1. Fatty areolar tissue.
2. The posterior belly of the omo-hyoid muscle.
3. Lymph Glands,
   - Lateral superior deep cervical.
   - Inferior deep cervical (Supraclavicular).
4. Arteries,[1]
   - Third part of subclavian.
   - Transverse cervical and its terminal branches.
   - Occipital (sometimes).
5. Veins,[2]
   - External jugular.
   - Transverse cervical.
   - Transverse scapular (O.T. suprascapular).
   - Termination of anterior jugular.
6. Nerves,
   - Accessory.
   - Branches of cervical plexus.
     - Lesser occipital.
     - Great auricular.
     - Nervus cutaneus colli.
     - To levator scapulæ.
     - ,, trapezius.
     - ,, scalenus medius.
     - ,, ,, posterior.
     - Supraclavicular.
   - To posterior belly of omo-hyoid, from ansa hypoglossi.
   - Trunks of brachial plexus.
   - Branches of the brachial plexus.
     - The nervus dorsalis scapulæ.
     - ,, long thoracic.
     - ,, suprascapular.
     - ,, nerve to the subclavius.

---

[1] The transverse scapular artery (O.T. suprascapular) lies posterior to the clavicle and is not, strictly speaking, in the triangle.

[2] The subclavian vein is posterior to the clavicle and therefore is not contained within the triangle.

Some of the contents of the triangle which are now displayed require further consideration.

Vena Jugularis Externa.—The external jugular vein is superficial except in the terminal part of its extent.

It commences on the surface of the sterno-mastoid, below the lower end of the parotid gland, by the union of the posterior auricular vein with a branch from the posterior facial vein. After its formation it runs downwards and backwards, across the sterno-mastoid, to the upper and anterior angle of the supraclavicular portion of the posterior triangle, in which it pierces first the superficial layer and then the second layer of the deep fascia, and it terminates in the subclavian vein (Figs. 12, 15).

As it crosses the sterno-mastoid it lies at first parallel with but anterior to the trunk of the great auricular nerve, then deep to the platysma, and whilst beneath the platysma it crosses either superficial or deep to the nervus cutaneus colli (Fig. 12). At the posterior border of the sterno-mastoid it sometimes receives a vein called the *posterior external jugular vein*, which descends across the upper part of the posterior triangle from the occipital region. Between the two layers of the deep fascia of the supraclavicular triangle it receives the transverse cervical, the transverse scapular and the anterior jugular veins, and it lies superficial to the lower roots of the brachial plexus; as it pierces the second layer of deep fascia, it lies superficial to the third part of the subclavian artery.

Immediately above its termination it is provided with a valve, consisting of two or three semilunar cusps. The dissector should note that, as the vein pierces the deep fascia, its wall is closely connected with the margin of the opening through which it passes; consequently when the fascia is stretched the lumen of the vein is expanded.

The Posterior Belly of the Omo-hyoid Muscle.—The posterior belly of the omo-hyoid muscle springs from the upper border of the scapula and upper transverse scapular ligament. It enters the posterior triangle, at its lower and posterior angle; runs upwards and forwards, at a variable distance from the clavicle, to the posterior border of the sterno-mastoid, and divides the posterior triangle into occipital and subclavian or supraclavicular portions. Either immediately behind or under cover of the posterior border of the

sterno-mastoid it joins the intermediate tendon which connects it with the anterior belly. Its nerve has already been seen entering its deep surface (p. 36). As it crosses the posterior triangle it lies superficial to the suprascapular nerve, the transverse cervical artery and the brachial plexus.

Nervus Accessorius (O.T. **Spinal Accessory**).—The portion of the accessory nerve which appears in the posterior triangle consists of fibres which arise from the cervical part of the spinal medulla, and with them are incorporated some filaments derived from the second cervical nerve. Before appearing in their present situation the spinal fibres entered the cranium through the foramen magnum and left it by passing through the jugular foramen; then they passed downwards and backwards, through the deeper fibres of sterno-mastoid, where they received the communication from the second cervical nerve. As already pointed out, the nerve usually enters the posterior triangle at the level of the union of the upper third with the lower two-thirds of the posterior border of the sterno-mastoid or at a slightly lower level. It runs downwards and backwards, through the triangle, along the line of the levator scapulæ, and disappears under the trapezius at the junction of the upper two-thirds with the lower third of its anterior border. As it enters the triangle the lesser occipital nerve turns round its lower border; and, as it crosses the triangle, it is joined by twigs from the third and fourth cervical nerves. It lies parallel with, but at a higher level than, the dorsalis scapulæ nerve (Fig. 12).

The Branches of the Cervical Plexus.—The dissector should note that whilst many of the branches of the cervical plexus lie within the area of the posterior triangle, the plexus itself is under cover of the upper part of the sterno-mastoid, where it will be exposed and studied when the sterno-mastoid is reflected. The branches which appear in the triangle are the *superficial branches*—(1) the lesser occipital; (2) the great auricular; (3) the nervus cutaneus colli, and (4) the supraclavicular nerves; and the *deep posterior branches*, that is, the nerves to (1) the scalenus medius and (2) the scalenus posterior; (3) the nerve to the levator scapulæ; (4) the branches to the trapezius, and (5) the communications to the accessory nerve.

The Third Part of the Subclavian Artery.—Only a portion of the third part of the subclavian artery is the triangle; the

lower and lateral part is behind the clavicle. The part in the triangle is situated deeply in the anterior inferior angle, and below the omo-hyoid muscle. It lies *deep to* the skin, superficial fascia, the platysma, deep fascia, the external jugular vein, the ends of the transverse scapular and transverse cervical veins, and the nerve to the subclavius muscle. The lowest trunk of the brachial plexus is *behind* it and separates it from the insertion of the scalenus medius. *Below*, it rests upon the first rib, against which it can be compressed, and, more medially, upon the cervical pleura.

The Brachial Plexus and its Supraclavicular Branches.— Only the upper portion of the brachial plexus lies in the region of the posterior triangle, *i.e.* the roots, the trunks, and some of the branches; the remainder lies either posterior to the clavicle or in the axilla. The cervical portion lies in the lower and anterior part of the posterior triangle, partly in the occipital and partly in the supraclavicular areas. The detailed study of the plexus should be left till the fifth day after the body has been placed upon its back, when the dissector of the head and neck will assist the dissector of the upper extremity to disarticulate the clavicle and to lay bare the whole of the plexus (p. 36); but it should be noted now— (1) that the cervical part of the plexus lies deep to the skin, superficial fascia, platysma and deep fascia, and that it is crossed superficially by the posterior belly of the omo-hyoid muscle, the external jugular vein, the transverse cervical artery and the transverse cervical and transverse scapular veins; (2) that part of the third portion of the subclavian artery is superficial to the lower part of the plexus; and (3) that behind the plexus is the lower part of the scalenus medius muscle.

The fourth day after the body has been placed upon its back should be devoted to the study of the temporal region and the scalp.

THE SCALP AND THE SUPERFICIAL STRUCTURES OF THE TEMPORAL REGION.

Under the term "scalp" are included the soft structures which cover the vault of the cranium above the temporal lines and anterior to the superior nuchal line. Its con-

stituent parts are arranged in five layers: (1) skin; (2) superficial fascia; (3) the epicranius, consisting of four muscular bellies, the two occipitales and the two frontales muscles, and the aponeurosis called the galea aponeurotica, which connects them together; (4) a layer of loose areolar tissue; (5) the periosteum, which in the region of cranium is called the pericranium. In the temporal region the wall of the cranium is much more thickly covered than in the scalp area, and it is possible to distinguish seven layers of soft tissues between the surface and the bone: (1) skin; (2) superficial fascia; (3) extrinsic muscles of the ear; (4) the thin lateral extensions

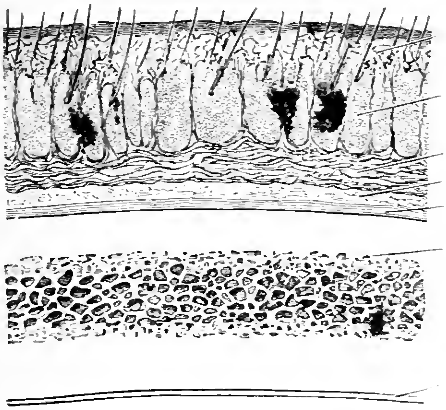

FIG. 13.—Section through the Scalp and Cranial Wall.

of the galea aponeurotica; (5) the strong temporal fascia; (6) the temporal muscle; (7) periosteum.

The Scalp.—The scalp and the superficial temporal region are richly supplied with blood vessels and nerves, which all enter from the periphery, passing into the superficial fascia after piercing the deep fascia of adjacent regions. As a consequence of that arrangement large flaps of the scalp may be torn from the centre towards the margin, but, so long as they remain attached at the periphery, their sources of vitality are not seriously interfered with, and, if they are cleaned and replaced, healing occurs rapidly and satisfactorily.

Dissection.—**The skin has already been removed from the anterior parts of the scalp and the temporal region. A median longitudinal incision must now be made through the skin of the posterior part of the scalp as far as the external occipital protuberance, and the flap on each side of the incision must be**

turned downwards and backwards to the superior nuchal line. When that has been done the dissector should examine the auricle of the external ear, and familiarise himself with its various parts before he commences the dissection of its extrinsic muscles.

Auricula.—The auricle consists of a thin plate of yellow fibro-cartilage, covered with integument. It is fixed in position by certain ligaments, and possesses two sets of feeble muscles—viz., one group termed the *extrinsic muscles*, passing to the cartilage from the aponeurosis of the epicranius and the mastoid process, and a second group in connection with the cartilage alone, and therefore called the *intrinsic muscles*.

The wide and deep depression which leads into the external acoustic meatus is the *concha*. The ridge behind

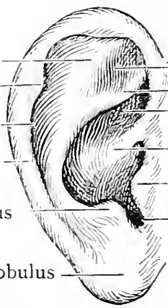

FIG. 14.—The Auricle.

the concha is the *antihelix*. It commences below, in a prominence called the *antitragus*. From the antitragus it curves upwards behind the concha, and it divides above into two crura which enclose a small depression called the *fossa triangularis*. Below the antitragus is the *lobule*, which forms the soft inferior extremity of the auricle. Its posterior border is continuous with the *helix*, which forms the incurved margin of the auricle. The helix ascends from the lobule to the summit of the auricle; then it descends, forming the anterior border of the upper part of the auricle, and, finally, it turns downwards and backwards above the external meatus, into the concha, which it partly divides into upper and lower portions. The part of the helix attached to the lobule is the tail of the helix (*cauda helicis*) and the part which passes from the anterior border of the auricle to the floor of the concha is the *crus helicis*. The depression which lies between the helix and the antihelix is the scaphoid

fossa or fossa of the helix. At the point where the posterior border of the auricle turns forwards towards the superior extremity there is, sometimes, a small triangular prominence which is known as *Darwin's Tubercle.* It represents the apex of the ear of an ordinary quadruped. In front of the meatus, and extending backwards to overshadow it, is a triangular prominence called the *tragus.* It is separated from the antitragus by a notch known as the intertragic notch (*incisura intertragica*). Numerous hairs grow from the posterior surface of the tragus. They become very prominent in the male after the middle period of life.

The ligaments and muscles connected with the auricle are:—

Ligaments, ...	Anterior. Superior. Posterior.	
Extrinsic muscles,	Auricularis anterior. Auricularis superior. Auricularis posterior.	
Intrinsic muscles,	Musculus helicis major. Musculus helicis minor. Musculus tragicus. Musculus antitragicus.	Upon the lateral face of the cartilage.
	Musculus transversus. Musculus obliquus.	Upon the cranial face of the cartilage.

Dissection.—After the dissector has noted the various parts of the auricle he should endeavour to display its extrinsic muscles; they are the *auriculares anterior* (O.T. *attrahens*), *superior* (O.T. *attollens*), and *posterior* (O.T. *retrahens*).

The auricularis anterior has already been dissected (see p. 14). It passes from the deep fascia of the temporal region to the front of the helix. To display the auricularis superior pull the upper part of the auricle downwards and carefully remove the superficial fascia above it. The muscle fibres spring from the lateral part of the galea aponeurotica and converge, as they descend, to the medial surface of the auricle in the region of the floor of the triangular fossa. After the auricularis superior has been cleaned pull the auricle forwards and clean the auricularis posterior. It is a thicker and more definite muscular bundle which springs from the mastoid portion of the temporal bone, above the mastoid process, and passes to the convexity on the medial surface of the auricle which corresponds with the floor of the concha. As the muscle is being cleaned one or more small *mastoid lymph glands* may be seen, and care must be taken to avoid injury to the branch from the posterior auricular nerve to the occipitalis part of the epicranius. It passes backwards either along the lower border of the auricularis posterior or under cover of that muscle.

The auriculares muscles are supplied by the facial nerve; the anterior and the anterior part of the superior by its temporal

branches, and the posterior and the posterior part of the superior by the posterior auricular branch. After the auriculares muscles have been defined remove the skin from the entire extent of the auricle to display the cartilage, the ligaments, and the intrinsic muscles.[1] Great care is required to make a successful dissection.

The **auricular cartilage** extends throughout the entire auricle, with the exception of the lobule and the portion between the tragus and the helix. Those portions are composed merely of integument, fatty tissue, and condensed connective tissue. The shape of the cartilage corresponds with that of the auricle itself. It shows the same elevations and depressions, and by its elasticity it serves to maintain the form of the auricle. But it also enters into the formation of the cartilaginous or lateral portion of the external acoustic meatus. By its medial margin this part of the cartilage is firmly fixed by fibrous tissue to the rough lateral edge of the auditory process of the temporal bone, but it does not form a complete tube. It is deficient above and anteriorly, and there the tube of the meatus is completed by tough fibrous membrane, which stretches between the tragus and the commencement of the helix.

In a successful dissection of the cartilage of the auricle, two other points will attract the attention of the student. The first is a deep slit, which passes upwards so as to separate the lower part of the cartilage of the helix, termed the *processus helicis caudatus*, from the cartilage of the anti-tragus. The second is a sharp spur of cartilage which projects forwards from the helix, at the level of the upper margin of the zygoma; it is termed the *spina helicis*.

The Ligaments of the Auricle.—The ligaments are three bands of fascia. The anterior passes from the spine of the helix to the root of the zygoma. The superior and posterior are both attached to the cartilage in the region of the concha; the former blends above with the temporal fascia, and the latter is attached to the mastoid portion of the temporal bone.

The Intrinsic Muscles of the Auricle.—The two muscles of the helix, and the tragicus and the antitragicus, are placed upon the lateral face of the cartilage. The transversus and the obliquus lie upon the cranial surface of the auricle.

The *musculus antitragicus* is the best-marked member of the lateral group. It lies upon the lateral surface of the antitragus, and its fibres pass obliquely upwards and backwards. Some fasciculi can be traced to the processus helicis caudatus.

The *musculus tragicus* is a minute bundle of short vertical fibres situated upon the lateral surface of the tragus. When well developed a slender fasciculus may sometimes be observed to pass upwards from it to the anterior part of the helix, where it is inserted into the spine of the helix.

The *musculus helicis major* is a well-marked band, which springs from the spina helicis, and extends upwards upon the anterior part of the helix, to be inserted into the skin which covers it.

The *musculus helicis minor* is a minute bundle of fleshy fibres which is placed upon the crus helicis as it crosses the bottom of the concha.

The *musculus transversus auriculæ* is found upon the cranial aspect of the auricle. It is generally the most strongly developed muscle of the series, and its fibres bridge across the hollow which, on this aspect of the auricle, corresponds to the antihelix.

---

[1] In most cases it will be advisable to defer this part of the dissection till the body is turned on its back for the second time, and to proceed at once to the dissection described on p. 47.

The *musculus obliquus auriculæ* is composed of some vertical fasciculi bridging across the depression which corresponds to the eminence of the lower limb of the antihelix.

Dissection.—After the auricle and its muscles and ligaments have been dissected and studied, follow the superficial temporal vessels and the auriculo-temporal nerve upwards from the point where they emerge from the upper end of the parotid gland to their terminal distribution in the scalp. Next, pull the auricle forwards and trace the posterior auricular nerve to its termination in the occipitalis muscle, and in the intrinsic and extrinsic muscles of the auricle, and the posterior auricular artery to its anastomoses with the occipital and superficial temporal arteries. After that part of the dissection is completed, turn to the anterior part of the scalp and find the medial and lateral branches of the supra-orbital nerve. The medial branch pierces the fibres of the frontalis and the lateral branch pierces the galea aponeurotica a little further back. Trace both branches backwards, through the superficial fascia, as far as possible; they extend to the level of the lambdoid suture. Then secure the supra-trochlear nerve, which pierces the frontalis above the medial margin of the orbit, and trace it upwards to its termination. With the branches of the supra-orbital nerve are branches of the supra-orbital artery, and the supra-trochlear nerve is accompanied by the frontal branch of the ophthalmic artery.

When the nerves and vessels in the anterior region have been cleaned, the head should be turned well over to the opposite side, and the branches of the occipital artery and the greater occipital nerve should be sought for in the posterior region; they radiate upwards and forwards from the upper extremity of the trapezius. After they have been secured, the occipitalis muscle must be cleaned. It springs from the lateral part of the superior nuchal line, and after a short course upwards and forwards, it terminates in the galea aponeurotica. The remains of the superficial fascia should now be removed from the surface of the galea aponeurotica (O.T. epicranial aponeurosis), and then the dissector should make a survey of the vessels and nerves which are met with in the scalp and in the superficial fascia of the temporal region.

Nerves and Vessels of the Scalp and of the Superficial Temporal Region.—Branches of ten nerves are found, on each side, in the superficial fascia of the region which lies above the supra-orbital margin, the zygomatic arch and the superior nuchal line. Five of the ten lie mainly anterior to the auricle and five posterior to it; and of each group four are sensory and one is motor. The four sensory nerves anterior to the auricle are all branches of the trigeminal nerve. They are the *supra-trochlear* and *supra-orbital* branches of the *first* or *ophthalmic division*; the *zygomatico-temporal branch* of the *maxillary* or *second division*; and the *auriculo-temporal branch* of the *mandibular* or *third division.* The motor nerve is the *temporal branch* of the *facial nerve.*

The four sensory nerves distributed mainly to the scalp area behind the auricle are the *great auricular* and the *lesser occipital* branches of the cervical plexus; the *greater occipital*, which is the medial division of the posterior ramus of the second cervical nerve; and the *third occipital*, not yet seen, but which will be displayed when the body is turned on its face. It lies medial to the greater occipital, and is the medial division of the posterior ramus of the third cervical nerve. The motor nerve distributed posterior to the auricle is the *posterior auricular branch* of the facial nerve.

The *arteries* distributed to the scalp are five in number on each side; they anastomose freely, and are derived, either indirectly or directly, from the internal and external carotid arteries. Three are distributed mainly anterior to, and two posterior to the region of the auricle. The three anterior to the auricle are the *frontal* and *supra-orbital branches* of the ophthalmic branch of the internal carotid, which accompany the supra-trochlear and supra-orbital nerves, respectively, and the *superficial temporal branch* of the external carotid. The superficial temporary artery divides into two main divisions, an anterior division, which accompanies the temporal branches of the facial nerve, and is usually a very tortuous vessel, and a posterior division, which accompanies the auriculo-temporal nerve, as it ascends, anterior to the auricle, towards the vertex of the cranium. The two arteries posterior to the auricle are both branches of the external carotid. They are the *posterior auricular*, which accompanies the posterior auricular branch of the facial nerve to the mastoid region and the posterior part of the parietal region, and *the occipital*, which is distributed to the occipital area and posterior part of the parietal area (Figs. 15, 17, 51).

The *terminations of the veins* which drain the blood from the scalp are as follows. The *frontal* and *supra-orbital veins* unite, at the medial border of the orbit, to form the *angular vein*, which is the commencement of the anterior facial vein, already dissected (p. 16). The blood it conveys passes eventually to the internal jugular vein. The *superficial temporal vein* accompanies the corresponding artery. It unites, immediately above the posterior root of the zygoma, with the middle temporal vein, which pierces the temporal fascia at that point. The trunk formed by the union of the superficial and middle temporal veins is the *posterior facial vein*, which

PLATE I

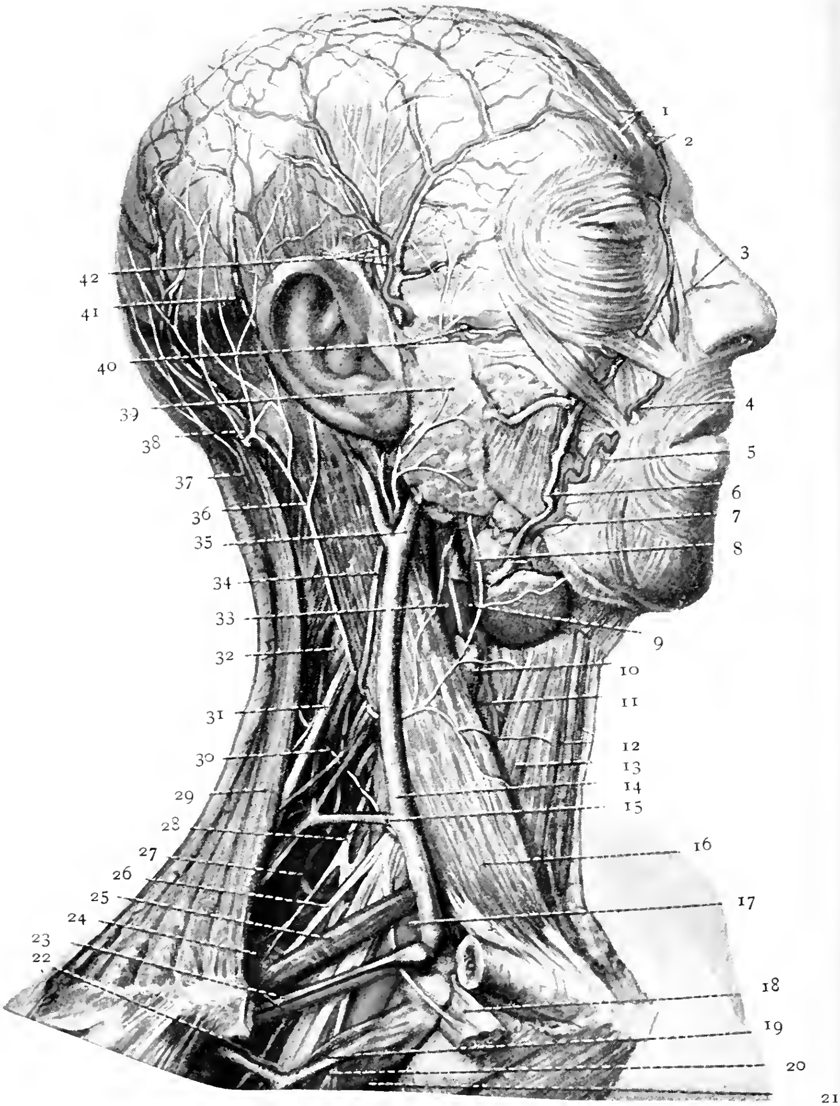

FIG. 15.

PLATE I

FIG. 15.—Dissection of the Head and Neck.

The sterno-mastoid muscle is left in position, the intermediate third or the clavicle has been removed and the medial part of the subclavius muscle has been turned downwards. Parts of the anterior, posterior and common facial veins have been removed.

1. Supra-orbital artery and nerve.
2. Frontal artery and vein.
3. Lateral nasal branch of external maxillary artery.
4. Superior labial branch of external maxillary artery.
5. Inferior labial branch of external maxillary artery.
6. Anterior facial vein.
7. External maxillary artery.
8. Cervical branch of facial nerve communicating with N. cutaneus colli.
9. External carotid artery.
10. Common facial vein.
11. Superior thyreoid artery.
12. Anterior jugular veins.
13. Omo-hyoid muscle (anterior belly).
14. External jugular vein.
15. Transverse cervical vein.
16. Sterno-mastoid muscle.
17. Subclavian artery.
18. Subclavius muscle with nerve.
19. Cephalic vein.
20. Lateral anterior thoracic nerve.
21. Axillary vein.
22. Acromial branch of thoraco-acromial artery.
23. Transverse scapular vessels.
24. First serration of serratus anterior muscle.
25. Omo-hyoid muscle (posterior belly).
26. Supra-scapular nerve.
27. Transverse cervical artery on scalenus medius muscle.
28. Upper root of long thoracic nerve.
29. Trapezius.
30. Ascending branch of transverse cervical artery which arose separately from the thyreo-cervical trunk.
31. Accessory nerve.
32. Levator scapulæ muscle.
33. Internal carotid artery.
34. Great auricular nerve.
35. Commencement of external jugular vein.
36. Lesser occipital nerve.
37. Third occipital nerve.
38. Greater occipital nerve and occipital artery.
39. Parotid gland.
40. Transverse facial vessels.
41. Posterior auricular vein.
42. Superficial temporal vessels and auriculo-temporal nerve.

descends through the parotid gland, emerges from under cover of its lower end and terminates, immediately below the angle of the mandible, by joining with the anterior facial vein to form the common facial vein. Whilst in the gland, it gives off a branch to the external jugular vein. The *posterior auricular vein* descends posterior to the external meatus and terminates in the external jugular vein. The *occipital vein* accompanies the occipital artery as far as the sub-occipital region, and ends in the sub-occipital venous plexus.

In addition to the arteries and veins there are numerous *lymph vessels* in the scalp, but they cannot be displayed by ordinary dissecting methods. Nevertheless, it is important that the student should remember their usual terminations. The lymph vessels of the anterior area end in small lymph glands which are embedded in the superficial surface of the parotid gland. Those of the posterior area terminate either in lymph glands which lie superficial to the mastoid part of the temporal bone, or in occipital lymph glands, which lie in the neighbourhood of the superior nuchal line.

Galea Aponeurotica (O.T. **Epicranial Aponeurosis**).—The galea aponeurotica is fully exposed as soon as the superficial fascia of the scalp is completely removed. It is a strong layer of aponeurosis connected anteriorly with the frontal bellies of the epicranius, posteriorly with the occipital bellies, and between the occipital bellies, with the external occipital protuberance and the medial parts of the superior nuchal lines, or with the supreme nuchal lines when they are present. Laterally, where it becomes thinner, it descends over the upper part of the temporal fascia, and gives origin to the anterior and superior auriculares muscles. It is so closely connected with the superjacent skin, by the dense superficial fascia, that the two cannot be separated, except with the aid of the cutting edge of the scalpel; but above the supra-orbital ridges, the temporal lines, and the superior nuchal lines it is only loosely connected to the pericranium by the layer of loose areolar tissue; therefore the three closely connected superficial layers, the skin, superficial fascia, and the galea aponeurotica, can easily be torn from the pericranium, a circumstance taken advantage of by the Indians who scalped their defeated foes. The looseness of the areolar tissue beneath the galea aponeurotica permits the latter to be drawn forwards and backwards by the alternate contractions

of the occipitalis and frontalis muscles, and, as it moves, it carries with it the skin and superficial fascia with which it is so closely blended.

Dissection.—After the dissector has studied the attachments of the galea aponeurotica, and after he has made himself thoroughly conversant with the nerve and vascular supply of the scalp, and has appreciated the fact that every part of its area is supplied by more than one nerve and that the blood vessels anastomose very freely together, he should next convince himself of the greater looseness of the areolar layer beneath the galea in the medial area and its greater denseness and closer attachment to the various parts of the superjacent epicranius, and the subjacent pericranium at the margins of the scalp area. He may do that by introducing the handle of a scalpel through a median incision in the galea, and passing it forwards and backwards and from side to side.

The Layer of Loose Areolar Tissue.—The layer of loose areolar tissue is the fourth layer of the scalp. It is but slightly vascular and is of loose texture, but is not equally loose over the whole area of the scalp; on the contrary, in the regions of the temporal and supra-orbital ridges it becomes much denser, and, at the same time, much more closely connected with the galea aponeurotica and the frontalis muscles, whilst posteriorly it disappears where the occipitalis muscles and the galea become attached to the superior nuchal lines. It is on account of those peculiarities that effusions of blood of inflammatory exudations in the areolar layer easily raise the greater part of the scalp from the bone, but such effusions do not readily pass from beneath the scalp into either the facial, temporal, or occipital regions.

On the fifth day after the body has been placed upon its back, the eighth after it was brought into the room, the dissector of the head and neck must assist the dissector of the upper extremity to display the whole extent of the brachial plexus and the origins of the branches which spring from it; and he should take the opportunity to revise his own knowledge of the plexus.

Dissection.—Detach the clavicular head of the sterno-mastoid from the clavicle, and displace the sternal head towards the median plane. When that has been done the anterior and upper parts of the sterno-clavicular joint capsule will be fully exposed, for the pectoralis major, which covered the lower part of the anterior surface, has already been reflected by the dissector of the upper extremity.

The sterno-clavicular joint is described on p. 37 of Vol. I. After the dissectors have noted that the fibres of the capsule run

medially and downwards from the clavicle to the sternum, the anterior, superior, and posterior portions must be divided close to the sternum, care being taken to avoid injury to the anterior jugular vein, which passes laterally close to the upper and posterior part of the joint. When the division is completed, elevate the sternal end of the clavicle by depressing the acromial end; introduce the knife into the cavity of the joint, close to the sternum, and carry it laterally below the clavicle, to detach the lower part of the articular disc from the sternum and the cartilage of the first rib, and to divide the lower part of the capsule and the costo-clavicular ligament, which lies immediately lateral to it. If the subclavius muscle has not already been detached, it also must be divided, and then the clavicle can be displaced laterally, and the whole extent of the plexus will be exposed.

Plexus Brachialis.—The brachial plexus is fully described on p. 39, Vol. I., and only a brief résumé of the main facts regarding it is given here. The plexus is formed by the last four cervical nerves and the larger part of the first thoracic nerve; it also receives a communication from the fourth cervical nerve and not uncommonly a small twig from the second thoracic nerve. Those various nerves constitute the *roots of the plexus*. The roots of the plexus emerge from between the scalenus medius and the scalenus anterior, and unite to form *three trunks*, upper, middle, and lower, which lie superficial to the scalenus medius, the lowest of the three being wedged in between that muscle posteriorly and the third part of the subclavian artery anteriorly. The *upper trunk* is formed by the fifth and sixth nerves and the communication from the fourth. The seventh nerve alone forms the *middle trunk*; and the *lowest trunk* is formed by the eighth cervical and first thoracic nerves and the communication from the second thoracic. Almost immediately after their formation the trunks divide into anterior and posterior divisions, and the divisions reunite to form *three cords*, lateral, medial, and posterior. The *lateral cord* is formed by the anterior divisions of the upper and middle trunks, the *medial cord* by the anterior division of the lowest trunk, and all three posterior divisions unite to form the *posterior cord*. The cords descend behind the clavicle and subclavius muscle, and through the cervico-axillary canal, to the level of the coracoid process of the scapula where the plexus terminates and each cord divides into two *terminal branches*. The terminal branches of the lateral cord are the lateral head of the median nerve and the musculo-cutaneous nerve. Those

of the medial cord are the medial head of the median and the ulnar nerve, and the posterior cord divides into the axillary

(O.T. circumflex) nerve and the radial (O.T. musculo-spiral). In addition to the terminal branches, *collateral branches* are

given off from the roots, the trunks and the cords; and the roots are connected with the middle and lower ganglia of the cervical part of the sympathetic trunk by grey rami communicantes. The branches given off from the roots are twigs of supply to the longus colli, the scalenus anterior, the scalenus medius, and the scalenus posterior, the roots of origin of the long thoracic nerve, which supplies the serratus anterior (O.T. magnus) and the dorsal scapular nerve (O.T. nerve to the rhomboids). The roots of the long thoracic nerve spring from the fifth, sixth, and seventh nerves; the upper two pierce the scalenus medius and the lowest passes anterior to that muscle. The three unite, behind the trunks of the plexus, to form the stem of the nerve, which descends behind the cords of the plexus into the axilla. The dorsalis scapulæ nerve arises from the lateral border of the fifth nerve; it disappears under cover of the levator scapulæ and supplies the two rhomboid muscles, and, sometimes, the levator scapulæ.

The branches from the trunks of the plexus are the suprascapular nerve and the nerve to the subclavius. They both spring from the upper trunk. The collateral branches of the three cords of the plexus are—(1) from the lateral cord: the lateral anterior thoracic nerve; (2) from the posterior cord: the upper and lower subscapular nerves and the thoracodorsal nerve (O.T. long subscapular); and (3) from the medial cord: the medial anterior thoracic, the medial cutaneous nerve of the arm (O.T. lesser internal cutaneous) and the medial cutaneous nerve of the forearm (O.T. internal cutaneous).

The Position of the Brachial Plexus.—The plexus lies (1) in the lower and anterior part of the posterior triangle of the neck, partly above and partly below the posterior belly of the omo-hyoid; (2) posterior to the clavicle; and (3) in the axilla. *Above the clavicle* it is covered by the skin, the superficial fascia and the platysma, branches of the supraclavicular nerves, the first layer of deep fascia, the external jugular vein, and the terminal parts of the transverse cervical and transverse (supra) scapular veins; the second layer of deep cervical fascia, the transverse cervical artery, the posterior belly of the omo-hyoid, the nerve to the subclavius, and the third part of the subclavian artery. *Behind the clavicle* it is crossed superficially by the transverse scapular artery (O.T.

suprascapular). *Below the clavicle* it is covered by the skin and superficial fascia, the platysma, the middle supraclavicular nerves, the deep fascia, the pectoralis major, the pectoralis minor, the cephalic vein, the branches of the thoraco-acromial artery, the costo-coracoid membrane, and the axillary artery and vein (Figs. 15, 16, 49, 51).

Its posterior relations in the neck are the scalenus medius and the long thoracic nerve. *Its posterior relations in the axilla* are the serratus anterior, the fat in the interval between the serratus anterior and the subscapularis, and, finally, the subscapularis itself.

After the brachial plexus has been examined, the clavicle must be replaced in position and the skin flap, reflected from the posterior triangle, must be replaced and fixed in position by a few sutures.

On the ninth day after the body is brought into the room, that is, on the sixth day after it has been placed on its back, it will be turned upon its face, with the thorax and the pelvis supported by blocks. The body will remain upon its face for five days, and during that period the dissectors of the head and neck must complete the dissection of the posterior part of the scalp; dissect the muscles, vessels and nerves of the back and the sub-occipital region; and remove and examine the spinal medulla.

THE DISSECTION OF THE BACK.

Dissection.—Make a median longitudinal incision from the external occipital protuberance to the seventh cervical spine, and a second incision laterally from the seventh cervical spine to the acromion, and throw the flap laterally. When that has been done the posterior triangle will be exposed from behind, and the dissector should take the opportunity of noting the positions of the contents and the constituent parts of the floor from that aspect. Afterwards he must look for the superficial nerves in the superficial fascia over the upper part of the trapezius. If the greater occipital nerve was not found during the dissection of the scalp, secure it at once, as it pierces the deep fascia covering the upper end of the trapezius, about midway between the external occipital protuberance and the posterior border of the mastoid portion of the temporal bone; trace it upwards through the dense superficial fascia of the scalp, and clean the branches of the occipital artery which are distributed in the same region. The third occipital nerve will be found in the superficial fascia between the greater occipital and the median plane. It is the medial division of the posterior ramus of the third cervical nerve,

and it supplies the skin of the medial and lower part of the posterior portion of the scalp and the adjacent part of the skin of the back of the neck. Trace it upwards to its termination, and downwards to the point where it pierces the deep fascia covering the trapezius. At a still lower level look for the medial divisions of the posterior rami of the other cervical nerves. They are variable in number and position, but those which are present will be found piercing the deep fascia over the trapezius, at a short distance from the median plane, and running downwards and laterally towards the posterior triangle.

After the cutaneous nerves have been found remove the remains of the superficial fascia and the deep fascia from the surface of the trapezius.

The Terminal Part of the Greater Occipital Nerve.—The greater occipital nerve is the large medial division of the posterior ramus of the second cervical nerve. It enters the posterior part of the scalp, after piercing the upper part of the trapezius and the deep fascia of the back of the neck, and it ramifies in the superficial fascia of the scalp over the occipital bone and the posterior part of the parietal bone. It is accompanied by the branches of the occipital artery, and it communicates with the great auricular and lesser occipital nerves.

Arteria Occipitalis.—After the occipital artery emerges from between the trapezius and the sterno-mastoid, at the apex of the posterior triangle, or pierces the upper part of the trapezius, its terminal part pierces the deep fascia of the back of the neck and enters the superficial fascia of the posterior part of the scalp. It anastomoses with its fellow of the opposite side, and with the posterior auricular and the superficial temporal arteries. As a rule, it breaks up into two main branches, a lateral and a medial. The medial branch gives off cutaneous twigs and a meningeal branch, which passes through the parietal foramen and anastomoses with a branch of the middle meningeal artery. Through the same foramen, passes an emissary vein which connects the occipital veins with the superior sagittal (longitudinal) sinus.

Musculus Trapezius.—The trapezius and latissimus dorsi constitute the first layer of the muscles of the back. Only that part of the trapezius which lies above the level of the seventh cervical spine belongs to the dissector of the head and neck; the lower part and the latissimus must be cleaned by the dissector of the arm, but the dissector of the head should take the opportunity to revise his knowledge of the whole origin and insertion of the trapezius. It arises from the medial third of the superior nuchal line of the occipital bone,

the external occipital protuberance, the whole length of the ligamentum nuchæ, the seventh cervical spine, the tips of all the thoracic spines and the corresponding supraspinous ligaments.

In the region of the seventh cervical spine the origin is more aponeurotic than elsewhere, and the fine tendinous

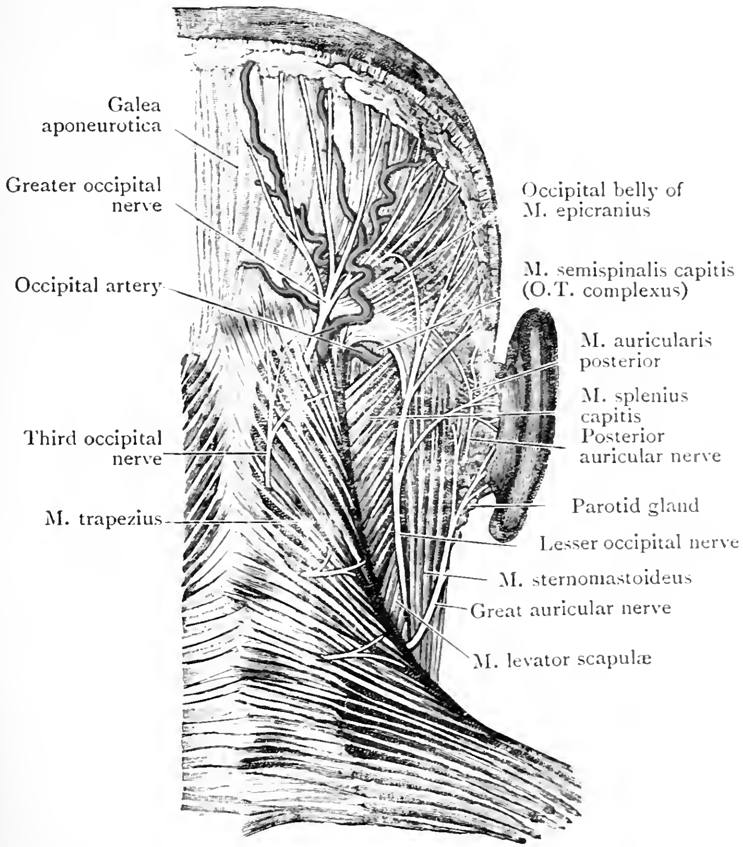

FIG. 17.—Superficial dissection of the Back of the Neck.

fibres of the muscles of the two sides form an ovoid aponeurotic area some two inches in length.

The upper fibres of the muscle descend in oblique curves and are inserted into the lateral third of the posterior border and the adjacent part of the superior surface of the clavicle; the middle fibres run horizontally, towards the shoulder, and are inserted into the medial border of the acromion and the upper lip of the posterior border of the spine of the

scapula. The lower fibres ascend, and terminate in a small triangular tendon which plays over the smooth triangle at the root of the scapular spine, and which is inserted partly into the lower lip and partly into the upper lip of the spine. The muscle is supplied by the accessory and the third and fourth cervical nerves. It draws the scapula medially and braces the shoulder backwards, raises the tip of the shoulder, or depresses the scapula and turns the glenoid fossa upwards, according to whether the middle, the upper, or the lower fibres are mainly in action.

Dissection.—On the second day after the subject has been placed on its face, the dissector, in conjunction with the dissector of the superior extremity, must reflect the trapezius muscle. First separate the muscle from the occipital bone, and then divide it about half an inch from the spines of the vertebræ. The muscle can now be raised and thrown laterally towards its insertion. On its deep surface the accessory nerve, the twigs of supply from the third and fourth cervical nerves and the ascending branch of the transverse cervical artery will be noticed. It is the duty of the dissector of the upper limb to dissect the structures mentioned, but the dissector of the head and neck should trace the artery to its origin from the transverse cervical artery.

The attachments of the levator scapulæ also must be defined. Two twigs from the third and fourth cervical nerves, which lie on its surface and finally enter its substance, have already been secured. Further, passing downwards under cover of the levator scapulæ muscle, the dorsal scapular nerve (O.T. nerve to the rhomboids) and the descending branch (O.T. posterior scapular) of the transverse cervical artery will be found. Almost invariably the dorsal scapular nerve gives one or two twigs to the levator scapulæ.

The levator scapulæ, the rhomboids, the posterior serrati and the splenius are classed as muscles of the second layer. The rhomboids and the lower part of the levator belong to the dissector of the arm; the remaining muscles are the property of the dissector of the head and neck.

Musculus Levator Scapulæ.—The levator scapulæ arises by four slips from the posterior parts of the transverse processes of the upper four cervical vertebræ. The slips unite to form an elongated muscle which extends downwards and backwards to be inserted into that portion of the vertebral border of the scapula which is placed above the level of the spine. Its nerve-supply is derived from the third and fourth cervical nerves, and also from the dorsal scapular nerve. The muscle raises the scapula and draws it towards the vertebral column.

The origin of the posterior belly of the omo-hyoid muscle may now be examined. It is attached to the upper transverse

ligament of the scapula and the adjacent part of the superior border of the bone. The transverse scapular artery (O.T. suprascapular) will be noticed passing over the upper transverse ligament, whilst the suprascapular nerve traverses the notch below it.

Dissection.—The *second day's* work is now completed, and on the *same day* the dissector of the upper limb must finish his share of the dissection of the back, so as to allow the dissector of the head and neck to begin the examination of the deeper structures on the dorsal aspect of the trunk.

Three days are allowed for the dissection of the deeper structures of the back. The work may be arranged in the following manner :—On the *first day*, all the muscles, fasciæ, nerves, and blood vessels of the back, with the exception of those in connection with the sub-occipital triangle, should be studied ; on the *second day*, the sub-occipital triangle may be examined ; and on the *third day* the medulla spinalis (O.T. spinal cord) must be displayed.

Commence work on the third day after the body has been placed on its face by cleaning the posterior serrate muscles. They are two in number, superior and inferior. The superior has been exposed by the removal of the trapezius, and the rhomboids and the inferior by the removal of the latissimus dorsi. Both pass from the spines of the vertebræ to the ribs, the superior in a downward and lateral direction to some of the upper ribs, and the inferior in an upward and lateral direction to the lower four ribs.

Musculi Serrati Posteriores.—The posterior serrate muscles are two thin sheets of fleshy fibres, which are placed upon the posterior aspect of the thoracic wall. The *serratus posterior superior* is much the smaller of the two ; it arises by a thin aponeurotic tendon from the lower part of the ligamentum nuchæ ; from the spinous process of the seventh cervical vertebra ; and from the spinous processes of the upper two or three thoracic vertebræ. It passes obliquely downwards and laterally, and is inserted into the outer surfaces of the second, third, fourth, and fifth ribs, a short distance anterior to their angles.

The *serratus posterior inferior* takes origin from the spinous processes of the last two thoracic and upper two lumbar vertebræ, and the supraspinous ligaments between them. The dissector will note, however, that this is not an independent and distinct attachment, but that it is effected through the medium of the lumbo-dorsal fascia, with which the aponeurotic tendon of the muscle blends. The muscle passes upwards and laterally and is inserted into the outer

surfaces of the lower four ribs. The superior serratus elevates the ribs to which it is attached, and is therefore a muscle of inspiration. It is supplied by the anterior rami of the second, third, and fourth thoracic nerves. The inferior serratus helps to fix the lower ribs and so facilitates the action of the diaphragm. Therefore, indirectly, it also is a muscle of inspiration. It is supplied by the anterior rami of the lower thoracic nerves.

Fascia Lumbo-dorsalis.—After the posterior serrate muscles have been displayed and examined on the third day after the

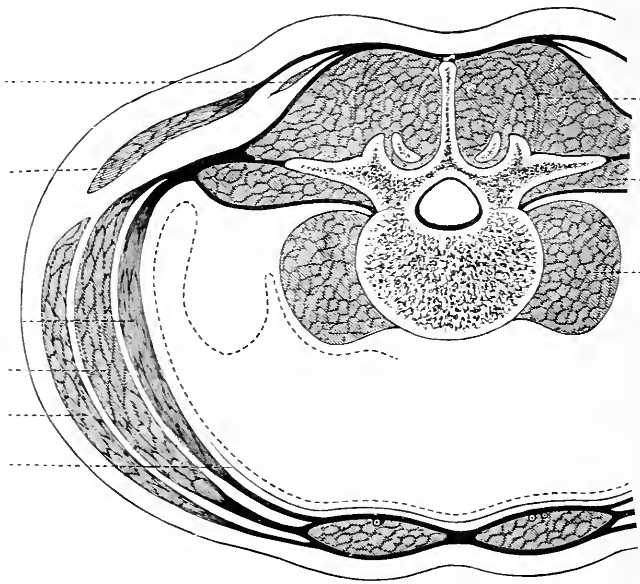

FIG. 18.—Diagram to show the Connections of the Lumbo-dorsal Fascia.

body is placed upon its face, the dissector of the head and neck should associate himself with the dissector of the abdomen in the examination of the lumbo-dorsal fascia. It is an aponeurotic layer, thin in the thoracic portion of its extent, but thick and strong in the lumbar and sacral regions. In all three regions it binds down the deeper muscles of the back to the sides of the spinous processes and to the transverse processes of the vertebræ.

The Thoracic Part of the Lumbo-dorsal Fascia (O.T. *Vertebral Aponeurosis*) is a thin transparent lamina which extends from the tips of the spines and the supraspinous ligaments to the angles of the ribs. At the upper end of

the thoracic region it dips beneath the serratus posterior superior into the neck, and at the lower end it blends with the aponeurosis of origin of the serratus posterior inferior, and, through that, becomes continuous with the posterior layer of the lumbar portion.

Dissection.—To display the lumbar part of the lumbo-dorsal fascia, take away the remains of the origin of the latissimus dorsi, which springs from its posterior surface, and then reflect the serratus posterior inferior by cutting through it at right angles to its fibres and turning it medially and laterally towards its origin and insertion. As the lateral part is turned aside secure its nerves of supply; they are derived from the ower intercostal nerves, and enter its deep surface. Next, remove the remains of the origin of the serratus posterior inferior, and then the posterior layer of the lumbar part of the lumbo-dorsal fascia will be completely exposed.

The Lumbar Part of the Lumbo-dorsal Fascia is separable into three lamellæ, a posterior, a middle, and an anterior. All three fuse together laterally, where they become connected with the internal oblique and the transversus abdominis muscles. The *posterior layer*, which is the strongest of the three, is a dense tendinous aponeurosis. It is continuous *above* with the thoracic part. *Below*, it is attached to the posterior part of the outer lip of the iliac crest, and to the dorsum of the sacrum and the coccyx. *Medially*, it is attached to the tips of the spines of the lumbar and sacral vertebræ; and *laterally* it blends with the posterior surface of the middle lamella (Fig. 18). The aponeurosis of origin of the latissimus dorsi and the serratus posterior inferior arise from its posterior surface.

Dissection.—Make a longitudinal incision through the posterior layer of the lumbar part of the lumbo-dorsal fascia, midway between its medial and its lateral borders. At each end of the longitudinal incision make a transverse incision, extending from the spines medially to the lateral border of the rounded mass of spinal muscles lying under cover of the fascia. Turn the medial part of the divided fascia towards the median plane, and verify its attachment to the vertebral spines and the supraspinous ligaments. Pull the lateral part aside, and at the lateral border of the mass of posterior spinal muscles note that it blends with a deeper middle lamella. Push the mass of posterior spinal muscles towards the median plane, and follow the middle lamella of the fascia to its attachment.

The *middle lamella* is attached, medially, to the tips of the transverse processes of the lumbar vertebræ; below, to the iliac crest, and, above, to the last rib. Laterally, it blends

with the posterior and anterior lamellæ, and, immediately lateral to its line of union with the posterior lamella, the internal oblique arises from its posterior surface. To expose it thoroughly the mass of posterior spinal muscles must be pushed medially.

Dissection.—After the middle lamella has been examined divide it longitudinally, close to its attachment to the tips of the transverse processes, and transversely along the line of the iliac crest, and turn it laterally. A considerable part of the posterior surface of the quadratus lumborum muscle will then be exposed. Displace the lateral border of the quadratus lumborum towards the median plane, and the anterior lamella of the lumbar part of the lumbo-dorsal fascia will be brought into view.

The *anterior lamella* of the lumbar part of the lumbo-dorsal fascia is attached, medially, to the anterior surfaces of the roots of the transverse processes of the lumbar vertebræ; laterally, it blends with the fused middle and posterior lamellæ to form the common aponeurosis of origin of the transversus abdominis muscle, and it is by means of the three lamellæ of the lumbar fascia that the latter muscle arises from the tips of the spines, and from the tips and the roots of the transverse processes of the lumbar vertebræ. The upper border of the anterior lamella becomes thickened, and extends, anterior to the quadratus lumborum, from the last rib to the transverse process of the first lumbar vertebra, as the *lateral lumbo-costal arch* (O.T. external arcuate ligament); the lower border blends with the ilio-lumbar ligament. The dissector should verify the various attachments by passing his fingers over the posterior surface of the lamella from its lateral to its medial border, and from its upper to its lower end.

Dissection.—After satisfying himself regarding the lamellæ of the lumbar part of the lumbo-dorsal fascia and their relations to the posterior spinal muscles, to the quadratus lumborum, and to the internal oblique and the transversus abdominis muscles, the dissector should make a longitudinal incision through the anterior lamella, and the peri-nephric fascia anterior to it; and, introducing his finger through the opening into the extra-peritoneal fatty tissue, he should scrape away the latter until he exposes the kidney, below the level of the last rib, and the adjacent part of the colon, which lies along the lower and lateral part of the kidney. After that has been done he should reflect the serratus posterior superior and secure its nerves of supply, which spring from the upper intercostal nerves and enter its deep surface; then he should remove the thoracic part of the lumbo-dorsal fascia and commence the study of the posterior spinal muscles, beginning with the splenius.

Musculus Splenius.—The splenius has a continuous origin from the lower half of the ligamentum nuchæ, and from the spines of the seventh cervical and upper six thoracic vertebræ. Its fibres pass obliquely upwards and laterally, forming a thick flat muscle, which soon divides into a cervical and a cranial portion, termed respectively the splenius cervicis and the splenius capitis.

The *splenius cervicis* turns forwards and is inserted, by tendinous slips, into the posterior tubercles of the transverse processes of the upper two or three cervical vertebræ, medial to the levator scapulæ.

The *splenius capitis* passes under cover of the upper part of the sterno-mastoid muscle, and gains insertion into the lower part of the mastoid portion of the temporal bone and into the lateral portion of the superior nuchal line of the occipital bone. To see the insertion, the sterno-mastoid muscle may be divided along the superior nuchal line, but it must not be detached from the temporal bone. The splenius capitis and cervicis bend the head and neck respectively backwards and turn them to the side on which the muscles lie. The splenius capitis and splenius cervicis are supplied by the posterior rami of the cervical nerves.

Dissection.—The deeper spinal muscles must now be dissected. Begin by reflecting the splenius muscle. Detach it from its origin and throw it laterally and upwards towards its insertion. Whilst doing that preserve the cutaneous branches of the cervical nerves which pierce the muscle.

When the splenius capitis is fully reflected, a small triangular space will be noticed close to the superior nuchal line of the occipital bone. Anteriorly, it is bounded by the longissimus capitis (O.T. trachelo-mastoid); posteriorly, by the lateral border of the semispinalis capitis (O.T. complexus); and above, by the superior nuchal line of the occipital bone. The floor of the little space is formed by the superior oblique muscle of the head, and it is traversed by the occipital artery, which in that part of its course gives off its descending branch (O.T. arteria princeps cervicis), and its meningeal branch.

The Third Layer of Muscles.—Under this head are included a series of muscular strands which stretch, with a greater or less degree of continuity, along the entire length of the dorsal aspect of the vertebral column. In the lumbar region they constitute a bulky fleshy mass which may be considered the main starting-point. The mass is the **musculus sacro-spinalis**, which has the following origins:—(1) from the spines of all the lumbar vertebræ; (2) from the supraspinous ligaments which bind the lumbar spines together; (3) from the dorsum of the sacrum and from the posterior sacro-iliac ligament; (4) from the posterior fifth of the iliac crest; (5) from the deep surface of the posterior layer of the lumbo-dorsal fascia. In great part the

superficial surface of this muscular mass is covered by and is adherent to the posterior layer of the lumbo-dorsal fascia.

Superiorly, the sacro-spinalis divides into three columns. The lateral column first separates from the general mass, and to it the name of *ilio-costalis* is given ; the intermediate column is termed the *longissimus*, and the medial column, which becomes quite distinct only as the upper part of the thoracic region is approached, is called the *spinalis.* The semispinalis muscle also is included in the third layer.

The **Ilio-costalis** is a column of muscular bundles which extends from the lumbar to the cervical region. It is separable into three segments, known, from below upwards, as the ilio-costalis lumborum, the ilio-costalis dorsi, and the ilio-costalis cervicis.

Ilio-costalis Lumborum.—The lumbar part of the ilio-costalis muscle and the longissimus dorsi become distinct at the level of the last rib, and the interval between them is marked by the exits of the lateral divisions of the posterior rami of lower thoracic nerves.

The ilio-costalis lumborum ends above in a series of six or seven slender tendons, which are inserted into the angles or the corresponding parts of the lower six or seven ribs.

The *Ilio-costalis Dorsi* (O.T. *Musculus Accessorius*) arises by six or seven slender tendons from the angles of the lower ribs, on the medial sides of the tendons of insertion of the ilio-costalis lumborum, and it is inserted by a series of similar tendons into the angles of the upper six ribs and to the transverse process of the seventh cervical vertebra.

The Ilio-costalis Cervicis (O.T. *Cervicalis Ascendens*) is the highest segment of the ilio-costalis. It arises, on the medial side of the ilio-costalis dorsi, by four slips which spring from the third, fourth, fifth, and sixth ribs ; it is inserted into the transverse processes of the fourth, fifth, and sixth cervical vertebræ.

> ***Dissection.*—To display the ilio-costalis properly, the dissector should first evert the lowest segment, and then in turn the middle and upper segments aside, but whilst doing that he must take care to preserve the lateral divisions of the posterior rami of the spinal nerves.**

The **Longissimus** is the middle and largest of the three muscle columns. It extends upwards, through the thoracic and cervical regions, to the head, and it also is separable into three segments : longissimus dorsi, longissimus cervicis, and longissimus capitis.

> ***Dissection.*—The interval between the longissimus and the spinalis is frequently difficult to define, but if the fascia is carefully cleaned from the lateral to the medial border of the longissimus, in the upper thoracic region, the separation will become apparent, and after it has been found the attachments of the longissimus must be defined. The muscle being displaced to the medial and lateral sides as may be necessary.**

Longissimus Dorsi.—The thoracic part of the longissimus possesses two rows of slips of insertion : a medial row of tendinous slips which are attached to the tips of the transverse processes of the thoracic and the accessory processes of the lumbar vertebræ, and a lateral row of muscular slips which are inserted into the lower ten ribs, on the lateral sides of their tubercles, and to the transverse processes of the lumbar vertebræ, and to the posterior surface of the middle lamella of the lumbar fascia.

Longissimus Cervicis (O.T. *Transversalis Cervicis*). — The cervical

portion of the longissimus springs from the transverse processes of the upper four thoracic vertebræ, and is inserted into the posterior tubercles of the transverse processes of the cervical vertebræ from the second to the sixth inclusive.

Longissimus Capitis (O.T. *Trachelo-mastoid*).—The longissimus capitis lies in the neck, under cover of the splenius. It arises, in common with the longissimus cervicis, from the transverse processes of three or four of the upper thoracic vertebræ, and, in addition, from the articular processes of a like number of the lower cervical vertebræ. The narrow, fleshy band which results is inserted into the posterior part of the mastoid portion of the temporal bone, under cover of the splenius capitis and sterno-mastoid muscles.

Musculus Spinalis.—The spinalis muscle is the most medial, shortest, and weakest of the three columns, and the most difficult to define. Below, it is intimately blended with the longissimus dorsi, but it may be regarded as taking origin by four tendons from the spines of the upper two lumbar and lower two thoracic vertebræ. The tendons end in a small muscular belly, which is inserted by a series of slips into a very variable number of the upper thoracic spines. It is closely connected with the subjacent semispinalis dorsi.

Spinalis Cervicis.—This upward prolongation of the spinalis is not always easy to define. It springs from the spines of the lower four cervical vertebræ and is inserted into the spines of the second, third, and fourth cervical vertebræ.

The various segments of the sacro-spinalis are supplied by the posterior rami of the spinal nerves. When the segments on one side only act they bend the vertebral column to that side, but when the segments on both sides act simultaneously they bend the vertebral column backwards.

***Dissection.*—The occipital artery has already been seen crossing the apex of the posterior triangle (p. 36), and its terminal branches have been dissected as they ramify in the scalp (p. 55). To expose the second part of the vessel, which extends from under shelter of the mastoid process, along the superior nuchal line of the occipital bone, to the point where it pierces the trapezius to become superficial, divide the longissimus capitis (O.T. trachelo-mastoid) a short distance below its insertion, and throw it upwards as far as possible, along with the splenius capitis; then clean the artery.**

Arteria Occipitalis.—In the region of the mastoid process the second part of the occipital artery is very deeply placed; indeed, no less than five structures lie superficial to it. These are (enumerating them in order from the vessel to the surface)—(1) the origin of the posterior belly of the digastric muscle; (2) the mastoid process; (3) the longissimus capitis; (4) the splenius capitis; and (5) the sterno-mastoid.[1] As the artery runs backwards, it very soon emerges from under cover of the first three of the structures mentioned, and a little farther on it leaves the shelter of the splenius, and is then covered by the sterno-mastoid alone. Issuing from

[1] It is not uncommon to find the artery between the splenius and the longissimus capitis, as in Fig. 20.

under cover of the posterior border of that muscle, the artery crosses the apex of the posterior triangle, and disappears under the trapezius, which it pierces afterwards, near the external occipital protuberance, to reach the scalp. Two muscles constitute its deep relations—viz., the insertions of the superior oblique and the semispinalis capitis (O.T. complexus) (Fig. 20).

The following *branches* may be traced from the second portion of the occipital artery: (1) ramus descendens (O.T. arteria princeps cervicis); (2) meningeal; (3) muscular.

The *descending branch* (O.T. *arteria princeps cervicis*) is a twig of some size, which passes medially to the lateral border of the semispinalis capitis (O.T. complexus); there it divides into a superficial and a deep branch. The former ramifies on the surface of the semispinalis capitis, whilst the latter sinks under that muscle, where it will be followed to its anastomosis with the deep cervical artery at a later stage in the dissection.

The small *meningeal branch* enters the posterior cranial fossa through the mastoid foramen, and supplies the dura mater and cranial wall in the mastoid region.

The *muscular twigs* go to the neighbouring muscles.

The *veins* corresponding to the occipital artery are two, or perhaps three, in number. They drain the blood from the occipital portion of the scalp, and open into the sub-occipital plexus, which is drained by the vertebral and deep cervical veins. The most lateral of the occipital veins frequently communicates with the transverse sinus (O.T. lateral sinus) through the mastoid foramen.

Dissection.—The semispinalis capitis, which has been exposed by the reflection of the splenius and the turning aside of the longissimus cervicis and longissimus capitis, must now be cleaned, and whilst that is being done and the attachments of the muscle are being defined, care must be taken of the medial divisions of the posterior rami of the second, third, fourth, and fifth cervical nerves. The first of the three—or, in other words, the greater occipital—from its great size, runs little risk of injury, but the others are liable to be overlooked. They all emerge from the substance of the muscle close to the median plane.

Musculus Semispinalis Capitis (O.T. *Complexus*).—The semispinalis capitis is the uppermost part of a muscular column consisting of three segments, which are spoken of collectively as the semispinalis, and individually as the semispinalis dorsi, the semispinalis cervicis, and the semispinalis

capitis. It belongs to the third layer of muscles, of which the greater number have been dissected already. The lower two segments will be dissected subsequently, but it is convenient to examine the semispinalis capitis at once. It is a thick fleshy mass which springs by tendinous slips from the transverse processes of the upper six thoracic vertebræ and the articular processes of the fourth, fifth, and sixth cervical vertebræ. Its massive upper extremity is inserted into a somewhat oval area on the occipital bone, between the superior and inferior nuchal lines close to the external occipital crest. It is separated from its fellow muscle of the opposite side by the ligamentum nuchæ; and its most medial part, which is to a certain extent distinct from the general mass, is divided into two bellies by an intermediate tendon, and is spoken of as the *biventer cervicis*. Occasionally the remainder of the muscle is also intersected by a tendinous septum.

The semispinalis capitis bends the head backwards. It is supplied by the posterior rami of the upper cervical nerves.

Dissection.—The semispinalis capitis must now be reflected by detaching it from the occiput and throwing it laterally. Care must be exercised, not only on account of the nerves which have been seen to perforate the muscle to reach the surface, but also on account of the structures which it covers. In its upper part it lies over the sub-occipital triangle and the muscles bounding it, whilst, below, it covers the semispinalis cervicis. A thick, dense fascia is placed over the subjacent parts, and in the fascia lie certain of the cervical nerves and the anastomosis between the descending branch of the occipital artery and the arteria profunda cervicis. The dissector must specially look for a small twig from the posterior ramus of the sub-occipital nerve which enters the deep surface of the upper part of the semispinalis capitis, and for a larger branch to the same muscle from the greater occipital nerve.

As soon as the twig to the semispinalis capitis is secured the dissector should cut out a small piece of the muscle to which the nerve goes, and leave it attached to the nerve to serve as a guide to the other branches of the sub-occipital nerve when the boundaries and contents of the sub-occipital triangle are being dissected (see p. 75).

Ligamentum Nuchæ.—When the semispinalis capitis has been turned aside the corresponding surface of the ligamentum nuchæ will be exposed (Fig 19). The ligament is a strong and fibrous partition, placed in the median plane, between the muscles on each side of the back of the neck. It represents a powerful elastic structure in quadrupeds, which helps to sustain the weight of the dependent head. In man, however, there is

not much elastic tissue developed in connection with it, and it appears to be a continuation upwards of the supraspinous ligament from the spine of the seventh cervical vertebra to the external occipital protuberance. In shape it is somewhat triangular. By its base it is attached to the external occipital crest; by its anterior border it is fixed by a series of slips to the posterior tubercle of the atlas, and to the bifid spines of the cervical vertebræ, in the intervals between their tubercles. Its

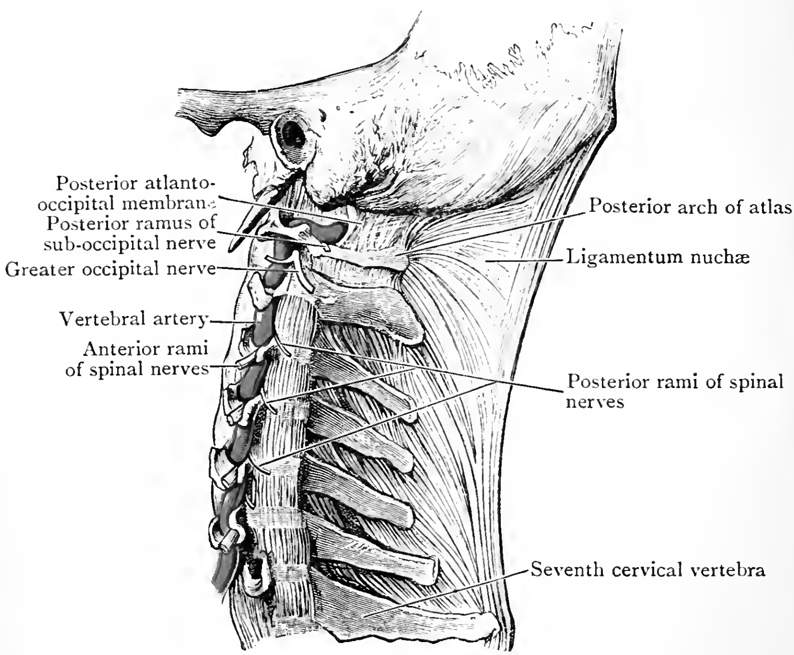

FIG. 19.—Dissection of the Ligamentum Nuchæ and of the Vertebral Artery in the Neck.

apex is attached to the spine of the seventh cervical vertebra, whilst its posterior border is, in a measure, free, and gives origin to the trapezius, rhomboid, serratus posterior superior, and splenius muscles

Arteria Profunda Cervicis.—The *deep cervical artery* springs from the costo-cervical branch of the subclavian, and reaches the back of the neck by passing between the transverse process of the last cervical vertebra and the neck of the first rib. At the present stage of the dissection it is seen ascending upon the semispinalis cervicis muscle and anastomosing

with the descending branch of the occipital. Both vessels anastomose with twigs from the vertebral artery.

The arteria profunda cervicis is accompanied by a large vein—the *vena profunda cervicis.* That vessel begins in the sub-occipital plexus, and it ends in the vertebral vein close to its termination. It reaches its termination by turning forwards under the transverse process of the last cervical vertebra.

Posterior Rami of the Spinal Nerves.—The nerves of the back must now be examined. They are the posterior rami of the spinal nerves. With *four* exceptions (viz., the first cervical, fourth and fifth sacral, and the coccygeal nerves), each posterior ramus will be found to divide into a *lateral* and a *medial division.*

Examine the nerves successively in the cervical, thoracic, and lumbar regions. It is well, however, to defer the dissection of the sacral and coccygeal nerves until the multifidus muscle has been studied.

Cervical Region.—In the neck the posterior rami of the spinal nerves are eight in number. The posterior ramus of the *sub-occipital* or *first spinal nerve* fails to divide into a medial and a lateral division. It lies deeply in the sub-occipital triangle, and will be examined when that space is dissected.

The posterior ramus of the *second cervical nerve* is very large. It appears between the vertebral arches of the first and the second cervical vertebræ. The posterior rami of the succeeding *six cervical nerves* arise from the corresponding spinal nerve-trunks in the intervertebral foramina, but they turn dorsally, on the medial sides of the posterior inter-transverse muscles, and appear in the intervals between the transverse processes.

The *lateral divisions* are of small size, and are entirely devoted to the supply of adjacent muscles.

The *medial divisions* are not all distributed alike, nor indeed do they present the same relations. Those from the *second*, *third*, *fourth*, and *fifth nerves* run medially towards the spinous processes, superficial to the semispinalis cervicis muscle, and under cover of the semispinalis capitis. When close to the median plane they turn backwards, pierce the semispinalis capitis, splenius, and trapezius muscles, and become superficial. In their course to the surface they give numerous twigs to the neighbouring muscles.

The medial division of the second nerve is remarkable for

its large size. It receives the special name of *greater occipital.* It will be noticed turning round the lower border of the inferior oblique muscle, to which it supplies some twigs. In passing to the surface it pierces the semispinalis capitis (O.T. complexus) and trapezius. To the former it gives several twigs. The distribution of this nerve on the occiput has been noticed already (p. 56).

The medial division of the third nerve also sends an offset to the occipital portion of the scalp (p. 55).

The medial divisions of the *lower three* posterior rami of the cervical nerves resemble the preceding, in so far that they take a course medially towards the spinous processes. They differ from them, however, in running deep to the semi-spinalis cervicis, and in being, as a rule, entirely expended in the supply of muscles.

Thoracic Region.—The posriteor rami of the thoracic nerves make their appearance in the intervals between the transverse processes. The *lateral divisions* proceed laterally, under cover of the longissimus muscle, and appear in the interval between the longissimus dorsi on the one hand and the ilio-costalis on the other. The *upper six or seven* of the nerves are exhausted in the supply of the intermediate and lateral columns of the sacrospinalis; the *lower five or six*, however, are considerably larger, and contain both motor and sensory fibres. After giving up their motor fibres to the muscles, they become superficial, by piercing the serratus posterior inferior and the latissimus dorsi, in line with the angles of the ribs. Their cutaneous distribution has already been examined by the dissector of the upper limb.

The *medial divisions* also are distributed differently in the upper and lower portions of the thoracic region. The *lower five or six* are very small, and end in the multifidus muscle. The *upper six or seven* pass medially between the multifidus and semispinalis, and, after supplying the muscles between which they are situated, they become superficial. In passing towards the surface they pierce the splenius, rhomboids, and trapezius muscles, and thus gain the superficial fascia, where they have been dissected already.

Lumbar Region.—The *medial divisions* of the posterior rami of the five lumbar nerves are small, and, like the corresponding twigs in the lower thoracic region, they have a purely muscular distribution. They end in the multifidus.

The *lateral divisions* sink into the substance of the sacro-spinalis, and are concerned in the supply of that muscle, and also of the lumbar intertransverse muscles. The lateral divisions of the *upper three lumbar nerves* are of large size, they become cutaneous by piercing the superficial lamella of the lumbo-dorsal fascia. They have already been traced by the dissector of the lower limb to the skin of the gluteal region. The lateral division of the fifth communicates with the corresponding branch of the first sacral nerve.

Blood Vessels of the Back.—In the *cervical region* the dissector has already noticed the arteria profunda cervicis, and the descending branch of the second part of the occipital artery. Deep in the sub-occipital region he will subsequently meet with a small portion of the vertebral artery. In addition, however, minute twigs from the vertebral artery may be discovered, in a well-injected subject, passing backwards in the intervals between the transverse processes, and also in the sub-occipital space. They supply the muscles, and anastomose with the other arteries in that region.

In the *thoracic region* the *posterior branches* of the aortic intercostal arteries and superior intercostal artery make their appearance between the transverse processes. Each of them passes dorsally in the interval between the body of a vertebra and the costo-transverse ligament. It is associated with the corresponding posterior ramus of a spinal nerve, and is distributed, with the nerve, to the muscles and integument of the back.

In the *lumbar region* similar branches are derived from the lumbar arteries. They are distributed in the same manner.

In both thoracic and lumbar regions, before reaching the back, the vessels under discussion furnish small *spinal branches* which enter the vertebral canal through the intervertebral foramina. These will be traced at a later period.

The *veins* accompanying the dorsal branches of the lumbar and intercostal arteries pour their blood into the lumbar and intercostal veins. They are of large size, being joined by tributaries from the posterior vertebral venous plexus, and also by others from within the vertebral canal.

Dissection.—The remainder of the third layer of spinal muscles must now be dissected. They are the semispinalis dorsi and semispinalis cervicis. The semispinalis cervicis is already exposed; but to display the semispinalis dorsi it is necessary to remove the spinalis dorsi muscle.

Musculus Semispinalis.—The *semispinalis dorsi* is composed of a series of muscular slips, with long tendons at each end, which arise from the transverse processes of the sixth to the tenth thoracic vertebræ. It is inserted into the spines of the upper four thoracic and lower two cervical vertebræ. The *semispinalis cervicis* lies under cover of the semispinalis capitis. It springs from the transverse processes of the upper five thoracic vertebræ, and is inserted into the spines of the second to the fifth cervical vertebræ. The slips composing the semispinalis muscles stretch over five or more vertebræ. The fibres of the semispinalis run upwards and medially. Therefore they turn the trunk and neck to the opposite side. They are supplied by the posterior rami of the spinal nerves.

***Dissection.*—The fourth layer of muscles must now be examined. It includes the multifidus, the rotatores, the interspinales, the intertransversales, and the recti and oblique muscles of the sub-occipital region. The latter have already been exposed by the reflection of the splenius and semispinalis capitis (complexus). To display the other members of the group the semispinalis dorsi and cervicis must be detached from the spines and drawn aside, and the sacrospinalis must be separated from the lumbar and sacral spines and turned laterally, if that has not already been done in tracing the nerves.**

Musculus Multifidus.—In the *lumbar* and *sacral regions* the multifidus will be seen to constitute a thick fleshy mass which clings closely to the vertebral spines. In that situation it has a very extensive origin—viz., (1) from the deep surface of the aponeurotic origin of the sacrospinalis; (2) from the posterior surface of the sacrum, as low as the fourth aperture; (3) from the posterior sacro-iliac ligament; (4) from the posterior superior spine of the ilium; and (5) from the mamillary processes of the lumbar vertebræ. In the *thoracic region* it takes origin from the transverse processes of the vertebræ, and in the *cervical region* from the articular processes of at least four of the lower cervical vertebræ. Each of the bundles of which the multifidus is composed passes upwards and is inserted into the whole length of the lower border of the spine of the second, third, or fourth vertebra above. The insertions extend from the fifth lumbar vertebra to the second cervical vertebra.

Musculi Rotatores.—The rotator muscles are a series of small muscles which are exposed when the multifidus is pulled aside. In the thoracic region each muscle springs from the root of a transverse process, and is inserted into the lamina of the vertebra immediately above, close to the root of the spinous process. Somewhat similar muscles have been described in the cervical and lumbar regions, and also a series of longer and more superficial slips which connect alternate vertebræ with each other. The multifidus and the rotatores are supplied by the posterior rami of the spinal nerves. They turn the trunk and neck towards the opposite side.

Musculi Interspinales et Intertransversarii.—The *interspinous muscles* can hardly be said to exist in the thoracic region, except in its upper and lower parts, where they are present in a rudimentary condition. In the neck they are arranged in pairs, occupying each interspinous interval, with the exception of that between the first and second cervical vertebræ. In the lumbar region also they are well marked and in pairs: there, they are attached to the whole length of the spinous processes. The *intertransverse muscles* are strongly developed in the lumbar region, and occupy the entire

length of the intertransverse intervals. Additional rounded fasciculi may be observed passing between the accessory processes; they are termed the *interaccessorii*. In the *thoracic region* intertransverse muscles—poorly developed—are found only in the lower three or four spaces. In the *cervical region* they are present in pairs and will be examined subsequently.

The interspinous muscles help to bend the vertebral column backwards. The intertransverse muscles bend it towards their own side. Both groups are supplied by the posterior rami of the spinal nerves.

Levatores Costarum.—The elevators of the ribs constitute a series of twelve fan-shaped muscles, which are classified as muscles of the thorax, but they are exposed when the longissimus and ilio-costalis are removed, and therefore should be examined now. They pass from the transverse processes to the ribs. The first muscle of the series springs from the tip of the transverse process of the last cervical vertebra, and, expanding as it proceeds downwards and laterally, it is inserted into the outer border of the first rib, immediately beyond the tubercle. Each of the succeeding muscles takes origin from the tip of a thoracic transverse process, and is inserted into the outer surface of the rib immediately below, along a line extending from the tubercle to the angle. The levatores costarum are muscles of inspiration. They are supplied by the anterior rami of the thoracic nerves.

Posterior Rami of the Sacral Nerves.—The posterior rami of the sacral nerves are very small. The *upper four* will be found emerging from the posterior sacral foramina; the *fifth* appears at the lower end of the sacral canal.

To expose the *upper three*, the multifidus, covering the upper three sacral apertures, must be carefully removed. Each of the three nerves will be found dividing in the usual manner into a medial and lateral division.

The *medial divisions* are very fine, and end in the multifidus.

The *lateral divisions* are somewhat larger, and join together to form a looped plexus upon the dorsum of the sacrum. The plexus communicates, above, with the lateral division of the posterior ramus of the last lumbar nerve and, below, with the posterior ramus of the fourth sacral nerve. Branches proceed from the loops to the surface of the sacro-tuberous ligament (O.T. great sacro-sciatic). Finally, they become superficial by piercing the glutæus maximus muscle, and they supply a limited area of skin over the gluteal

region. They have already been examined by the dissector of the lower limb.

The posterior rami of the *lowest two* sacral nerves do not separate into medial and lateral divisions. They are very small, and, after communicating with each other, and also with the *coccygeal nerve*, they distribute filaments to the parts on the posterior aspect of the lower portion of the sacrum and on the dorsal aspect of the coccyx.

Twigs from the lateral sacral arteries accompany the sacral nerves and anastomose with twigs from the gluteal arteries.

Posterior Ramus of the Coccygeal Nerve.—This is a slender twig which emerges from the inferior opening of the sacral canal, and, after being joined by a filament from the last sacral nerve, is distributed on the dorsum of the coccyx.

Posterior Vertebral Venous Plexus.—A plexus of veins is situated upon the superficial aspect of the vertebral arches subjacent to the multifidus muscle. Blood passes to it from the integument and muscles of the back, and is conveyed by it, in the thoracic and lumbar regions, into the posterior tributaries of the intercostal and lumbar veins. In the neck it is especially well marked, and there blood is emptied from it into the vertebral veins. In an ordinary dissection, the plexus is not very noticeable, but it is a source of serious trouble during operations upon the vertebræ (comp. p. 79).

Dissection.—The fourth day after the body is placed upon its face must be devoted to the dissection of the sub-occipital triangle, and the fifth day to the display of the medulla spinalis (O.T. spinal cord), its membranes, nerve-roots, and blood vessels.

If the dissector is pushed for time, it is better that he should proceed at once to expose the spinal medulla (p. 78), and defer the dissection of the sub-occipital region until the head and neck have been removed from the trunk.

Sub-Occipital Space.—The sub-occipital space is a small triangular area, exposed by the reflection of the semi-spinalis capitis (O.T. complexus) and the splenius muscle. It is *bounded* by three muscles—(1) the rectus capitis posterior major forms its upper and medial boundary; (2) the obliquus inferior limits it below; and (3) the obliquus superior bounds it above and to the lateral side. *Its floor* consists of two structures—viz., the posterior arch of the atlas and the thin posterior atlanto-occipital membrane. It *contains* a portion of the vertebral artery and the posterior ramus of the sub-occipital or first cervical nerve (Fig. 20).

Dissection.—The dissection of the sub-occipital space is difficult, because the connective tissue in which its contents lie is dense. The first structures to secure are the posterior ramus of the sub-occipital nerve and its branches. The branch to the semispinalis capitis was retained, with a small piece of the

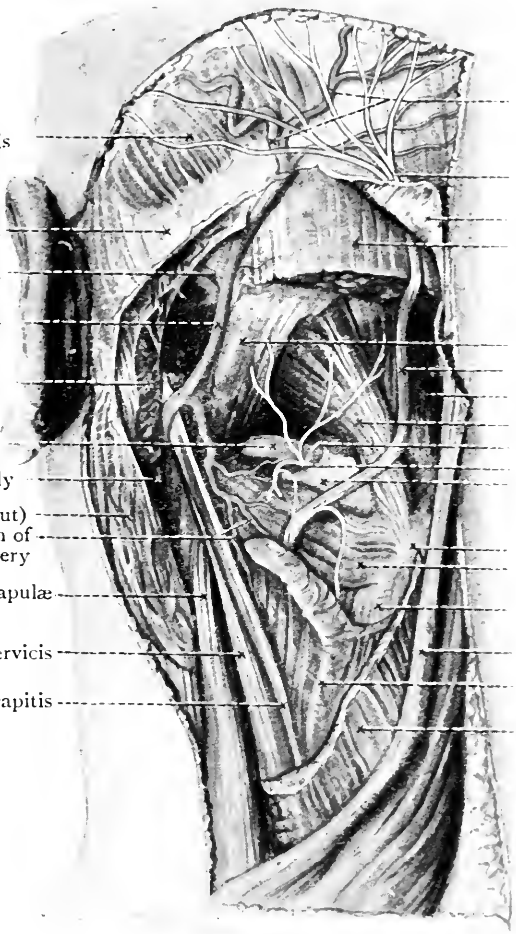

FIG. 20.—Dissection of the Sub-Occipital Region. Note that in this specimen the occipital artery was superficial to the longissimus capitis muscle.

muscle attached to it, when the semispinalis was reflected (p. 67); trace it into the space until it joins the posterior ramus, then follow the other branches from the posterior ramus to their terminations. One branch passes upwards to the superior oblique; one passes upwards and medially to supply the rectus capitis posterior major and the rectus capitis posterior minor; each of the two twigs into which it divides enters the superficial surface of the muscle it supplies, and the twig to the rectus

capitis posterior minor crosses the superficial surface of the rectus capitis posterior major; the last branch passes downwards to the inferior oblique muscle; it supplies that muscle and sends a twig of communication to the greater occipital nerve, which in its turn sends a communicating twig to the medial branch of the posterior ramus of the third cervical nerve. The union of the posterior rami of the first three cervical nerves thus formed is called the *posterior cervical plexus*. After the nerves mentioned have been secured and cleaned, clean the muscles which form the boundaries of the space, and afterwards remove the remains of the fascia from the space, and display the posterior arch of the atlas, the third portion of the vertebral artery, which lies on the upper surface of the posterior arch of the atlas above the trunk of the sub-occipital nerve, and the posterior atlanto-occipital ligament.

Musculus Rectus Capitis Posterior Major.—The major posterior rectus muscle of the head springs by a pointed origin from the spine of the epistropheus (O.T. axis), and expanding as it passes upwards and laterally, it is inserted into the occipital bone along the lateral portion of the inferior nuchal line and into the surface immediately below. It draws the head backwards and rotates it to the same side. It is supplied by the posterior ramus of the sub-occipital nerve.

Musculus Rectus Capitis Posterior Minor.—The minor rectus capitis posterior muscle is a small fan-shaped muscle, placed to the medial side of, and overlapped by, the rectus major. It takes origin from the tubercle on the posterior arch of the atlas, and is inserted into the medial part of the inferior nuchal line of the occipital bone and into the surface between that line and the foramen magnum. It draws the head backwards and is supplied by the posterior ramus of the sub-occipital nerve (Fig. 20).

Musculus Obliquus Capitis Inferior.—The inferior oblique muscle extends from the extremity of the spine of the epistropheus to the posterior border of the transverse process of the atlas. The greater occipital nerve will be seen hooking round its lower border. It is supplied by the posterior ramus of the sub-occipital nerve and it rotates the atlas and the head to the same side.

Musculus Obliquus Capitis Superior.—The superior oblique muscle springs from the transverse process of the atlas, and is inserted into the occipital bone, in the interval between the nuchal lines, below and to the lateral side of the semispinalis capitis. Acting with its fellow of the opposite side it draws the head backwards. Acting alone it turns the head slightly

to the opposite side. It is supplied by the posterior ramus of the sub-occipital nerve (Fig. 20).

The Actions of the Deep Muscles of the Back.—The dissector will have noted that many of the deep muscles of the back, such as the various prolongations of the sacro-lumbalis, run vertically upwards; others run upwards and medially, viz., the semispinalis dorsi and cervicis and the multifidus spinæ. A third group, exemplified by the splenius capitis and cervicis, the serratus posterior inferior and the inferior oblique muscle, run upwards and laterally. When the muscles which run vertically upwards contract, on one side only, they bend the vertebral column to that side, but if the muscles of both sides act simultaneously they bend the vertebral column backwards. When the muscles which run upwards and laterally contract they turn the head or trunk to the same sides, whilst those which run upwards and medially turn the head or trunk to the opposite side. The muscles which lie at the sides of the sub-occipital space need further consideration. They act either upon the occipito-atlantal joints, the joints between the first and second cervical vertebræ, or upon both sets of joints. At the occipito-atlantal joints backward and forward movement and a slight oblique movement whereby the head is turned a little to one or the other side take place. The main movement between the atlas and the second cervical vertebræ is a movement of rotation, the atlas carrying the head rotating around the dens of the second vertebræ.

The rectus capitis posterior minor and the superior oblique act on the joints between the atlas and occipital bone only: the rectus capitus posterior minor producing backward movement only and the superior oblique backward movement and a very slight oblique movement which turns the head slightly towards the opposite side. The inferior oblique acts only on the joints between the atlas and the second vertebra, turning the head to the same side. The rectus capitis posterior major alone acts on both sets of joints, drawing the head backwards and turning it to the same side.

Posterior Ramus of the Sub-Occipital Nerve.—The posterior ramus of the sub-occipital nerve does not divide into medial and lateral divisions. It enters the sub-occipital triangle by passing dorsally, between the posterior arch of

the atlas and the vertebral artery, and at once breaks up into branches which go to supply five muscles—viz., the two posterior recti, the two oblique muscles, and the semispinalis capitis. In addition to the muscular twigs it gives a *communicating*, and sometimes a *cutaneous filament*.

The *communicating branch* generally proceeds from the nerve to the obliquus capitis inferior, and joins the greater occipital nerve. The *cutaneous branch*, when present, accompanies the occipital artery to the integument over the occiput.

Arteria Vertebralis.—Only the third portion of the vertebral artery lies in the sub-occipital triangle. It emerges from the foramen in the transverse process of the atlas, and runs backwards and medially in the groove upon the posterior arch of that bone. As it passes medially it lies immediately posterior to the lateral mass of the atlas and above the sub-occipital nerve. It leaves the space by passing anterior to the thickened lateral extension of the posterior atlanto-occipital membrane, which runs from the posterior arch of the atlas to the posterior lip of its articular process and is called the oblique ligament of the atlas; then the artery pierces the dura mater and enters the spinal canal (Fig. 37).

Small branches proceed from the vertebral artery, as it lies in the sub-occipital space, to supply the parts in its immediate neighbourhood, and to anastomose with the descending branch of the occipital artery and the arteria profunda cervicis.

Dissection to open the Vertebral Canal.—The first step consists in thoroughly cleaning the laminæ and spinous processes upon both sides. The multifidus must be completely removed from the dorsum of the sacrum. At the same time the posterior rami of the nerves must be retained, so that their continuity with the various spinal nerve-trunks may be afterwards established. The dissector should then remove the posterior wall of the vertebral canal *in one piece* by sawing through the laminæ on each side, and dividing the ligamenta flava, from the third cervical vertebra down to the lower opening of the sacral canal.

In making this dissection the student must attend to the following points:—(1) the cut should be directed through the laminæ close to the medial sides of the articular processes; (2) the saw must be used in an oblique plane, so that the cut through the laminæ slants slightly medialwards; (3) as the cervical laminæ are cut through, the head and neck should hang over the end of the table, and be flexed as much as possible, whilst the saw is worked from below upwards; (4) in the case of the lumbar region, where, indeed, most difficulty will be met, a high

block must be placed under the abdomen of the subject, whilst the blocks supporting the chest and pelvis are removed. It will probably be necessary at this point to have recourse to the hammer and chisel.

The laminæ and spinous processes which are thus removed are connected with each other by the ligamenta flava and the supraspinous and interspinous ligaments. They should be laid aside for the present. A description of the ligaments will be found on p. 269. Whilst the specimen is fresh, however, the dissector should test the high elasticity of the ligamenta flava by stretching them.

Between the dura mater and the walls of the canal, the dissector will notice a quantity of loose areolar tissue and soft fat. The latter is especially plentiful in the sacral region, where it somewhat resembles the marrow in the medullary cavity of a long bone. Great numbers of large veins and minute arteries ramify in this areolo-fatty material.

Arteriæ Spinales.—In a well injected subject a minute spinal artery will be seen entering the vertebral canal through each intervertebral foramen. These arteries are derived from different sources in the different regions of the vertebral column. In the cervical region they come from the vertebral artery; in the thoracic region, from the posterior branches of the intercostal arteries; in the lumbar region, from the dorsal branches of the lumbar arteries. They supply the spinal medulla and its meninges, the bones, the periosteum, and the ligaments; and their arrangement is very much the same in each of the three regions.

Each spinal artery may be looked upon as giving off *three main twigs*; one of them, termed the *pre-laminar branch*, is a very small twig which ramifies upon the deep surface of the vertebral arches and ligamenta flava. Another, the *neural branch*, can be followed to the dura mater, which it pierces immediately above the point of exit of the corresponding spinal nerve. It divides into two twigs, one of which passes along the posterior and the other along the anterior root of the nerve to join the plexus in the spinal pia mater. The third, the *post-central branch*, is carried medially, anterior to the dura mater, towards the posterior surface of the vertebral bodies; it divides into an ascending and a descending twig which anastomose with the corresponding twigs above and below, and in that manner a continuous series of minute arterial arcades is formed, from which branches pass medially to form a series of cross anastomoses with the corresponding vessels of the opposite side.

In the *cervical region* small branches from the ascending cervical artery also find their way into the vertebral canal; whilst in the *sacral portion* of the canal the dissector will find branches from the lateral sacral arteries.

Internal Vertebral Venous Plexus.—The internal vertebral venous plexus extends along the whole length of the vertebral canal, and consists essentially of four subsidiary longitudinal plexuses, two anterior and two posterior, which anastomose freely with each other.

The *posterior plexuses* are united by many cross branches, which run along the deep aspect of the vertebral arches and ligamenta flava. Above, they communicate with the occipital sinus, whilst, all the way down, they are connected with the *posterior vertebral venous plexus* by wide channels which pierce the ligamenta flava. Laterally, they send branches through the intervertebral foramina to join the posterior branches of the intercostal and lumbar veins.

The *anterior plexuses* cannot be dissected whilst the medulla spinalis

(O.T. spinal cord) and its membranes are *in situ*, but it is convenient to describe them at this stage. Indeed, the dissection is one of considerable difficulty, even under the most advantageous circumstances. They form two main longitudinal venous channels, placed one upon each side of the posterior longitudinal ligament of the vertebral bodies, and they are joined by transverse branches which cross the median plane, anterior to that ligament, opposite each vertebral body. Each transverse vein receives large tributaries from the interior of the vertebra. Superiorly, each of the main longitudinal channels communicates with the occipital sinus or the basilar plexus, within the cranium; and each of the posterior channels gives off a branch which emerges above the posterior arch of the atlas to join the commencement of the vertebral vein. Opposite the various intervertebral fibro-cartilages the anterior plexus sends off branches which run towards the intervertebral foramina, where they join with corresponding branches of the posterior plexus, to form the intervertebral veins which accompany the corresponding spinal nerves.

Meninges of the Medulla Spinalis (Fig. 21).—The medulla spinalis, like the brain, with which it is continuous, is enveloped by three membranes, termed *meninges*. The most external investment is a strong fibrous membrane called the *dura mater*; the second, in order from without inwards, is a non-vascular tunic termed the *arachnoid*; whilst the third and most internal is the *pia mater*. The three membranes are directly continuous with the corresponding investments of the brain.

Dissection.—The outer surface of the dura mater must now be cleaned. This is effected by the removal of the loose areolar tissue, soft fat, and posterior internal vertebral from the vertebral canal. It is necessary, also, to define carefully the numerous lateral prolongations which the membrane gives to the spinal nerves.

Dura Mater Spinalis (Fig. 21).—In the vertebral canal the dura mater constitutes an exceedingly dense and tough fibrous tube, which extends from the foramen magnum above, to the level of the second or third piece of the sacrum below. It is separated from the walls of the vertebral canal and its lining periosteum by an interval which is filled with loose fat and areolar tissue and the internal vertebral venous plexus. Even before the membranous tube is laid open, the dissector can readily satisfy himself that it forms a very loose sheath around the spinal medulla and the nerve-roots which form the cauda equina below the spinal medulla; in other words, it is very capacious in comparison with the volume of its contents. Its calibre, moreover, is by no means uniform; in the cervical and lumbar regions it is considerably wider than in the thoracic region, whilst in the sacral canal it rapidly contracts

and finally ends, at the level of the second sacral vertebra, by blending with the *filum terminale*, a fibrous thread which is prolonged downwards through the sacral canal from the extremity of the medulla spinalis (O.T. spinal cord).

The cylindrical tube of spinal dura mater does not lie free within the vertebral canal, but its attachments do not in any way interfere with the free movement of

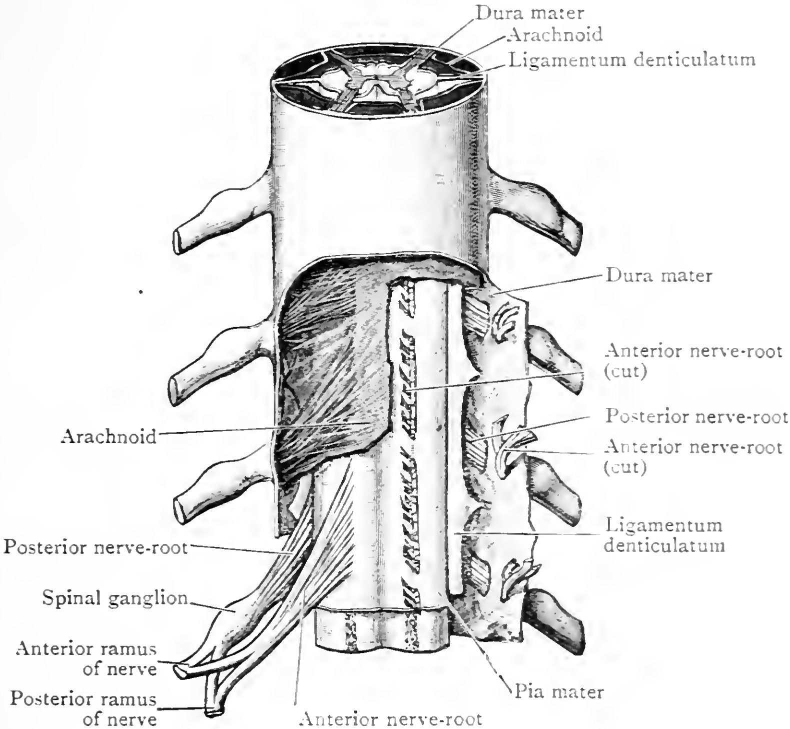

FIG. 21.—Membranes of the Medulla Spinalis (O.T. Spinal Cord), and the mode of origin of the Spinal Nerves.

the vertebral column. *Above*, the dura mater is firmly attached around the margin of the foramen magnum, and to the bodies of the second and third cervical vertebræ; *below*, the filum terminale, on which the dura mater terminates, can be traced as far as the dorsum of the coccyx, where it is lost by blending with the periosteum. On each side, the spinal nerve-roots, as they pierce the dura mater, carry with them, into the intervertebral foramina, tubular sheaths of the membrane, which are attached to the margins of the foramina; whilst, anteriorly, loose fibrous prolongations—more numerous

above and below than in the thoracic region—connect the tube of dura mater to the posterior longitudinal ligament of the vertebral column. No connection of any kind exists between the dura mater and the vertebral arches or ligamenta flava.

Dissection.—**The tube of dura mater may now be opened with the scissors. The incision should be carried through the membrane in the median plane. Care, however, must be taken not to injure the delicate arachnoid, which is subjacent.**

Cavum Subdurale.—The subdural cavity is the capillary interval between the dura mater and the arachnoid (Fig. 20). The deep surface of the dura, which is turned towards the space, is smooth, moist and polished. The dissector will notice, upon each side, the series of apertures of exit for the roots of the spinal nerves. They are ranged in pairs opposite each intervertebral foramen. The subdural space is prolonged laterally, for a short distance, upon each of the nerve-roots, and has a free communication with the lymph paths present in the nerves.

Viewed from the inside of the tube of dura mater, each of the two nerve-roots belonging to a spinal nerve is seen to carry with it a special and distinct sheath. When examined, however, on the outside of the tube of dura mater, they appear to be enveloped in one sheath, because the two sheaths are closely held together, on the outside, by intervening connective tissue which can be removed with a little careful dissection. When that is done, the two tubular sheaths will be seen to remain distinct as far as the ganglion on the posterior root of the nerve. At that point they blend with each other.

Arachnoidea Spinalis (Fig. 20).—The arachnoid, like the dura mater, forms a loose, wide investment for the spinal medulla. Unlike the dura, however, it is remarkable for its great delicacy and transparency. The sac is most capacious, and can be demonstrated most easily towards its lower part, where it envelops the extremity of the spinal medulla and the collection of long nerve-roots which constitute the *cauda equina*. Make an incision into it, and insert the handle of the scalpel, or, better still, inflate the sac with air by means of a blowpipe. Above, the spinal arachnoid becomes continuous, through the foramen magnum, with the arachnoid membrane of the brain. On each side, it is prolonged upon the various nerve-roots, contributing a tubular sheath to each. It ends, below, at the level of the second sacral vertebra, by fusing with the filum terminale.

Cavum Subarachnoideale (Fig. 20).—The sub-arachnoid

cavity is the wide space between the arachnoid and pia mater. It is occupied by a variable amount of cerebro-spinal fluid, and is directly continuous with the cranial sub-arachnoid space through the foramen magnum. Three incomplete septa partially subdivide the spinal sub-arachnoid space into compartments. One of the septa is a median partition, called the *septum subarachnoideale*, which connects the arachnoid with the pia mater covering the posterior aspect of the spinal medulla. In the upper part of the cervical region the sub-arachnoid septum is represented merely by a number of strands passing between the two membranes; in the lower part of the cervical region and in the thoracic region it is almost complete. The other two septa are the ligamenta denticulata. They spread laterally, one from each side of the medulla spinalis, and will be studied with the pia mater.

Dissection.—Take away the arachnoid from a portion of the spina medulla, and proceed to the study of the pia mater.

Pia Mater Spinalis.—The pia mater of the spinal medulla is a firm vascular membrane, which adheres closely to the surface of the medulla spinalis (O.T. spinal cord). It is thicker and denser than the pia mater of the brain, largely owing to the addition of an outer layer of fibres, which run chiefly in a longitudinal direction. It is folded into the antero-median fissure of the medulla spinalis; and the posterior median septum of the medulla spinalis is firmly attached to its deep surface. Anteriorly, in the median plane, it is thickened to form a longitudinal glistening band, which receives the name of the *linea splendens*. Of course, that can be seen only after the medulla spinalis has been removed from the vertebral canal. The blood vessels of the medulla spinalis lie between the two layers of the pia mater before they enter the substance of the spinal medulla; and the various spinal nerves receive from it closely fitting sheaths which blend with their connective-tissue coverings.

Ligamentum Denticulatum (Figs. 20 and 22).—There are two dentate ligaments, one on each side. Each stretches laterally from the corresponding side of the medulla spinalis and connects it with the dura mater. Its *medial attachment* extends in a continuous line, between the anterior and posterior nerve-roots, from the level of foramen magnum, above, to the level of the body of the first lumbar vertebra,

below. Its *lateral margin* is widely serrated or denticulated. From twenty to twenty-two denticulations may be recognised; the highest is attached to the margin of the foramen magnum. They occur in the intervals between the spinal nerves, and, pushing the arachnoid before them, they are attached by their pointed extremities to the inner surface of the dura mater.

The ligamenta denticulata maintain the medulla spinalis (O.T. spinal cord) in the middle of the tube of dura mater, and partially subdivide the sub-arachnoid space into an anterior and a posterior compartment. In the anterior compartment the anterior nerve-roots pass laterally; the posterior compartment contains the posterior nerve-roots, and is imperfectly subdivided into two lateral subdivisions by the septum sub-arachnoideale.

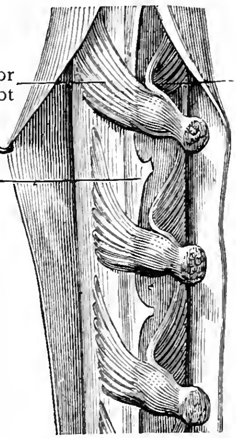

FIG. 22.—Lateral view of the Medulla Spinalis, Dura Mater, and Ligamentum Denticulatum. (Hirschfeld and Leveillé.)

Medulla Spinalis (O.T. Spinal Cord).—The spinal medulla itself may now be studied *in situ*. It is almost cylindrical in form but is slightly flattened anteriorly and posteriorly. It extends from the foramen magnum, where it is continuous with the medulla oblongata of the brain, to the lower border of the body of the first or the upper border of the body of the second lumbar vertebra. Its lower end rapidly tapers to a point, and is termed the *conus medullaris*. From the extremity of the conus a slender filament, termed the *filum terminale*, is prolonged downwards to the dorsal surface of the coccyx.

In the female the average length of the medulla spinalis is 43 cm.; in the male it is 45 cm. (18 *inches*).

Throughout the greater part of the thoracic region, the medulla spinalis presents a uniform girth, but in the cervical and lower thoracic regions it shows marked swellings,

termed respectively the *intumescentia cervicalis* and *intumescentia lumbalis*. The *cervical enlargement*, which is connected with the nerves of the superior extremities, is the more evident of the two. It begins at the upper end of the medulla spinalis (O.T. spinal cord), attains its greatest breadth (13 or 14 mm.) opposite the fifth or sixth cervical vertebra, and subsides opposite the second thoracic vertebra. The *lumbar enlargement* is connected with the nerves of the inferior extremities. It begins at the level of the tenth thoracic vertebra, attains its maximum transverse diameter (11 to 13 mm.) opposite the last thoracic vertebra, then it rapidly tapers into the conus medullaris.

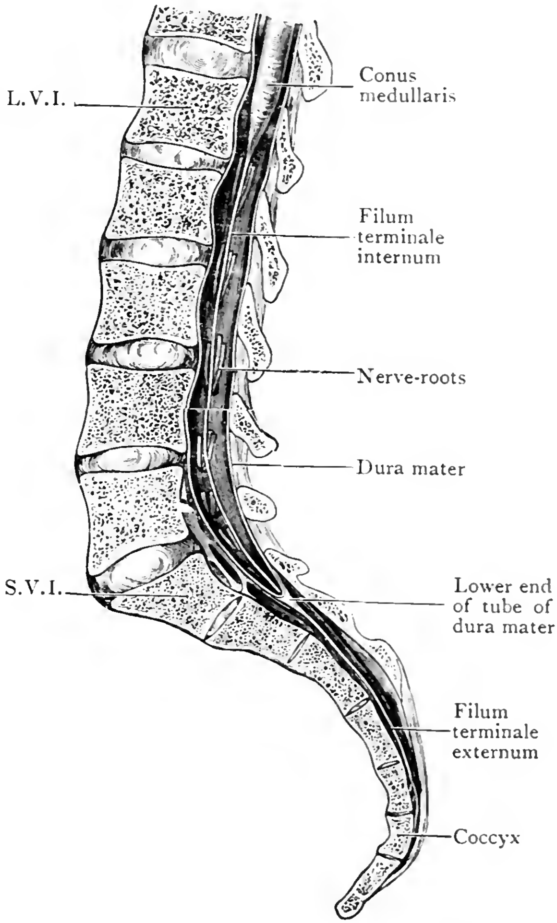

FIG. 23.—Sagittal section through the lower part of the Vertebral Canal.

Filum Terminale. — The delicate thread-like terminal filament lies amidst the numerous long nerve-roots which occupy the lower part of the vertebral canal, but it can readily be distinguished from them (1) by its silvery glistening appearance, and (2) by its continuity with the extremity of the *conus medullaris* (Fig. 23).

It is composed chiefly of pia mater, although the central canal of the medulla spinalis is prolonged down in its interior for nearly half its length, and nervous elements can be traced

in its substance for a like distance. The *linea splendens* and the lower ends of the *ligamenta denticulata* may also be considered to be continued into it. At the level of the second or third sacral vertebra it pierces the tapered end of the tube of dura mater, and receives an investment from it; finally it reaches the lower end of the sacral canal, where it terminates by blending with the periosteum on the dorsal surface of the coccyx or the last piece of the sacrum.

In length it measures about 15 cm. (6 *inches*). The part within the tube of dura is termed the *filum terminale internum*, the portion outside is the *filum terminale externum*.

Nervi Spinales.—Thirty-one spinal nerves take origin from each side of the medulla spinalis (O.T. spinal cord). They are classified into five groups, according to the vertebræ with which they are associated. The thoracic, lumbar, and sacral nerves correspond in number with the vertebræ in each of those regions—thus, there are twelve thoracic, five lumbar, and five sacral nerves, each of which issues from the vertebral canal below the vertebra with which it numerically corresponds. In the cervical region, however, there are eight nerves. The first of them comes out between the occiput and the atlas, and is therefore distinguished by the special name of the *sub-occipital nerve.* There is only one coccygeal nerve on each side.

Spinal Nerve-Roots (Figs. 21 and 24).—Each spinal nerve springs from the side of the spinal medulla by *two roots*—an *anterior* and a *posterior.* Except in the case of the sub-occipital nerve (where the posterior root is sometimes absent), the posterior nerve-root is the larger of the two. In addition, the posterior root is distinguished by possessing an oval ganglion, termed the *spinal ganglion.* There is, also, a wide physiological difference between the two roots—the posterior root is composed of afferent fibres; the anterior root consists of efferent fibres. Immediately beyond the ganglion the two roots unite to form the *spinal nerve-trunk*, which contains a mixture of both efferent and afferent nerve-fibres.

The *mode of attachment* of the two nerve-roots to the side of the medulla spinalis is somewhat different in the two cases. In each instance they are attached by several separate *fila radicularia*, which spread out from each other as they approach their attachments. In the case of the posterior root the fila enter the spinal medulla consecutively, along a continuous

straight line and at the bottom of a slight furrow. The fila of the anterior root, on the other hand, are not so regularly placed. They emerge from the medulla spinalis over an area of some breadth. The portion of the medulla spinalis which stands in connection with a pair of nerves receives the name of a "neural segment."

It will be noted that the *size* of the nerve-roots differs greatly. The lower lumbar and upper sacral nerve-roots are much the largest, whilst the lower sacral and the coccygeal roots are the smallest. In the cervical region the roots increase in size from above downwards, but more rapidly in the lower members of the group; in the thoracic region the roots of the

7. Anterior ramus.
7'. Posterior ramus.

first nerve are large, but those which succeed it are small and of uniform size.

In *relative length*, and in the *direction* which they follow in the vertebral canal, the nerve-roots also show great differences. The differences are due to the medulla spinalis being so much shorter than the canal in which it lies. In the upper part of the cervical region the nerve-roots are short, and proceed laterally and almost horizontally. Below the upper cervical region the nerve-roots become more oblique, and the lower the origin of the nerve the longer is its course in the canal. The arrangement of the lower thoracic, the lumbar, sacral, and coccygeal nerve-roots is particularly characteristic. They are exceedingly long, and descend vertically from the lower portion of the medulla spinalis, forming the bundle which is called the *cauda equina*.

The origins of the eight cervical nerves lie between the level of the atlas and the level of the spine of the sixth cervical vertebra; the origins of the first six thoracic nerves extend from the sixth cervical to the third thoracic spine; the origins of the lower six thoracic nerves lie between the third and the ninth thoracic spines; and the origins of the lumbar and sacral nerves are between the ninth thoracic and the first lumbar spine.

Mode of Exit of Spinal Nerves from Vertebral Canal.—The lower six cervical nerves, the thoracic nerves, and the lumbar nerves make their exit through the intervertebral foramina; whilst each of the two rami of the upper four sacral nerves finds its way out by a sacral foramen. The upper two cervical nerves, the fifth sacral nerve, and the coccygeal nerve, however, follow a different course. The sub-occipital emerges by passing over the posterior arch of the atlas, and the second cervical nerve by passing over the vertebral arch of the epistropheus (O.T. axis). The fifth sacral and the coccygeal nerve leave the sacral canal through its lower aperture (Fig. 25).

Dissection.—The nerve-roots of one or two spinal nerves in each region should be followed into the corresponding intervertebral foramina. That can be easily done by snipping away the articular processes with the bone-forceps. The position of the ganglion on the posterior root, the connections of the sheath of dura mater, the union of the two roots to form the spinal nerve-trunk, and the division of the trunk into the anterior and posterior rami can then be studied. An attempt should also be made, at the same time, to discover the minute *ramus meningeus*. It is a fine twig which is formed by the union of a small filament from the spinal nerve-trunk with a minute branch from the sympathetic trunk. It takes a recurrent course through the intervertebral foramen to end in the bones and periosteum and meninges of the vertebral canal.

Ganglia Spinalia.—The spinal ganglia are oval swellings developed upon the posterior nerve-roots, just before they unite with the anterior roots to form the spinal nerve-trunks. They are found upon the posterior roots of all the nerves, except, occasionally, those of the sub-occipital and the coccygeal nerves.

The ganglia are formed upon the posterior nerve-roots as they lie in the intervertebral foramina, except in the cases of the first two cervical and the sacral and coccygeal nerves. The ganglia of the first two cervical nerves lie upon

the posterior arch of the first and the vertebral arch of the second cervical vertebræ, respectively; the ganglia of the sacral nerves are placed within the sacral canal, but outside the tube of dura mater. The ganglion on the posterior root of the coccygeal nerve is inside the tube of dura mater.

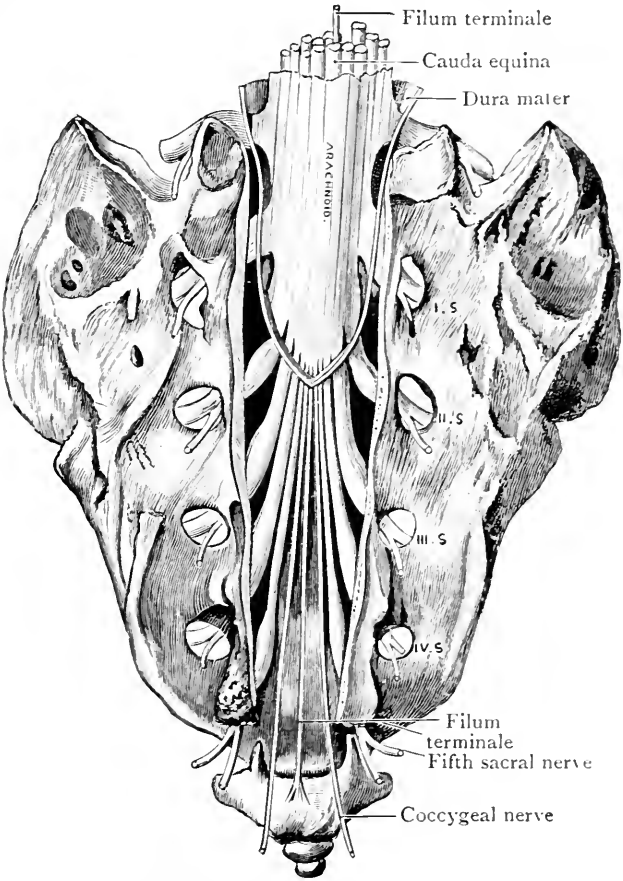

FIG. 25.—The Sacral Nerve-roots (lower part of Cauda Equina) and the Membranes in relation to them. (After Testut.) The posterior wall of Sacral Canal has been removed.

Spinal Nerve-Trunks.—The trunks of the spinal nerves are formed by the union of the anterior and posterior nerve-roots immediately beyond the spinal ganglia. The union takes place in the case of the coccygeal and sacral nerves in the sacral canal; in the lumbar, thoracic, and lower six cervical nerves, in the intervertebral foramina; and in the case of the first two cervical nerves, on the arches of the atlas and epistropheus respectively.

The nerve-trunk is exceedingly short in most cases; indeed, it divides almost immediately into its *anterior* and *posterior rami*. In the cases of the sacral and coccygeal nerves, the subdivision takes place in the sacral canal, and the spinal nerve-trunks of those nerves are distinctly longer than the trunks of the nerves which occupy a higher level.

The distribution of the posterior rami has already been examined (p. 69).

Dissection.—At this stage the dissector may adopt one of two methods in the further treatment of the medulla spinalis and the nerves which spring from it. If the medulla spinalis is fresh and in such a condition that it may be successfully hardened, it is best to transfer it at once to the preservative fluid. If, on the other hand, it is soft and not fit for proper preservation, it should be removed with all its membranes and nerve-roots, and placed in a cork-lined tray filled with water. There is no method by which the arachnoid, the pia mater, the ligamenta denticulata, and the nerve-roots can be so well studied as this.

To remove the medulla spinalis, the dissector should divide the spinal nerves as they lie in the intervertebral foramina, and in such a manner that as long a piece as possible of each nerve remains attached to the dura mater and the spinal medulla. Wherever it is possible the ganglia should be taken with the nerves. The same rule applies to the sacral nerves also. The medulla spinalis and its membranes should then be cut across at the highest limit of the vertebral dissection. Pull upon the dura mater in order to lift the whole specimen from the vertebral canal, and then transfer it to the water-bath. Slit up the dura mater along the median plane anteriorly, and turn aside the edges of the incision. By fixing the dura mater with pins to the cork at the bottom of the tray, the dissector can conduct the further dissection with great advantage, and can display in turn the arachnoid, and the pia mater with the ligamenta denticulata.

Arteries of the Medulla Spinalis (O.T. **Spinal Cord**).—It is only when the arterial injection is particularly good that the spinal arteries can be made out satisfactorily.

Numerous small arteries are supplied to the medulla spinalis. They are the *anterior* and *posterior spinal arteries*, which spring from the vertebral artery in the cranium, and a series of *lateral spinal arteries*, which reach the side of the medulla spinalis and are derived from different sources in each region. *In the neck* they come from the vertebral, ascending cervical, and deep cervical arteries; and *in the thoracic* and *lumbar regions*, from the posterior branches of the intercostal and lumbar arteries. By the anastomoses of the various arterial twigs, five longitudinal trunks are formed upon the surface of the medulla spinalis. One lies in the median

plane anteriorly, and may be termed the *antero-median artery*. The other four are placed in relation to the sulci along which the posterior nerve-roots enter the medulla spinalis. One runs downwards anterior to the line of entrance of those roots, and the other posterior to it, on each side of the medulla spinalis. The posterior vessels may, therefore, be termed the *postero-lateral longitudinal vessels.*

The *antero-median vessel* is formed above by the union of the two anterior spinal branches of the vertebral arteries. One of them is larger than the other, and takes a much greater share in the formation of the median trunk. Below the level of the fifth pair of cervical nerves the continuity of the median vessel depends upon the reinforcements which it obtains from the lateral spinal vessels. The number of lateral spinal arteries which join the median vessel is very variable. The majority of them end on the nerve-roots; only five to ten reach the median vessel. The *antero-median artery* runs downwards, under cover of the linea splendens of the pia mater. Its calibre is uniform throughout, and where the medulla spinalis ends it proceeds onwards for some distance upon the filum terminale.

The *postero-lateral arteries* on each side of the medulla spinalis are formed in the upper part of the cervical region by the bifurcation of the corresponding posterior spinal branch of the vertebral artery. Lower down their continuity is maintained by twigs which reach them, on the posterior roots of the spinal nerves, from the lateral spinal arteries. It may be regarded as a rule, that where a lateral spinal artery gives a branch to one of the postero-lateral arterial trunks, it does not furnish another to the antero-median arterial trunk. Nevertheless, the different lateral spinal arteries are in connection, directly or indirectly, with the longitudinal trunks on the anterior and posterior aspects of the medulla spinalis. The postero-lateral vessels end at the lower extremity of the medulla spinalis.

From the five main arterial channels which thus extend along the spinal medulla spring numerous anastomosing twigs which ramify in the pia mater.

Veins of the Medulla Spinalis.—The veins of the spinal medulla are small and numerous, and their disposition cannot be said to correspond with that of the arteries. They are very tortuous, and form a plexus with elongated meshes. Six more or less perfect longitudinal venous trunks may be noticed on the surface of the medulla spinalis in connection with the venous plexus; two of them are median, and are placed respectively on the anterior and posterior aspects. The anterior trunk runs upwards under cover of the antero-median spinal artery. The other four are lateral, and are situated two on each side, in relation, respectively, to the anterior and posterior nerve-roots.

Upon each side, the veins of the medulla spinalis effect

communications with the veins in the vertebral canal by means of small twigs which run laterally on the nerve-roots.

How to distinguish the anterior from the posterior surface of the medulla spinalis.

Anterior Surface.	Posterior Surface.
1. Linea splendens.	1. The postero-lateral arteries, in relation to the posterior nerve-roots.
2. Single anterior spinal artery, in median plane.	2. Fila of origin of posterior nerve-roots entering the medulla spinalis along a straight and continuous line, and at the bottom of a distinct sulcus.
3. Anterior nerve-roots, smaller than posterior, and springing by fila which emerge from the medulla spinalis, not in a continuous straight line, but irregularly over an area of some width.	3. Posterior nerve-roots, larger than the anterior, and provided with ganglia.

Preservation of the Medulla Spinalis.—If the medulla spinalis is in a fit state for preservation, it should be immersed for a few weeks in methylated spirit, to which a small amount (4 per cent.) of formalin has been added. When sufficiently firm, the dissector should endeavour to learn something of its internal structure by making transverse sections across it at different levels, and inspecting the cut surface closely with the naked eye, or with the aid of a magnifying glass.

Internal Structure of the Medulla Spinalis.—The medulla spinalis is composed of an inside core of grey matter which is surrounded on all sides by an external coating of white matter, and a good deal can be learned by a naked-eye inspection of cross sections through it made in different regions and at different levels.

In such sections the *antero-median fissure* and the *postero-median septum* and *sulcus*, which partially divide it along the whole of its length into right and left halves, become obvious.

The antero-median fissure is much shorter than the postero-median septum. It dips dorsally to a commissure of white matter, the *anterior white commissure*, which connects the white matter of the two halves of the medulla spinalis; and it contains a fold of pia mater and branches of the anterior spinal vessels. The postero-median sulcus is a shallow furrow which runs along the posterior surface of the medulla spinalis in the median plane, and the postero-median septum extends from the bottom of the sulcus to a transverse grey commissure called the *posterior commissure*, which connects the two halves of grey matter.

The two halves of the medulla spinalis, thus marked off from each other, are to all intents and purposes symmetrical, and they are joined by a more or less broad band or commissure which intervenes between the anterior fissure and the posterior septum.

An inspection of the surface of each half of the medulla spinalis brings into view a groove or furrow at some little distance from the postero-median sulcus; it is called the *postero-lateral sulcus.* Along the bottom of that groove the fila of the posterior nerve-roots enter the medulla spinalis (O.T. spinal cord) in accurate linear order. There is no

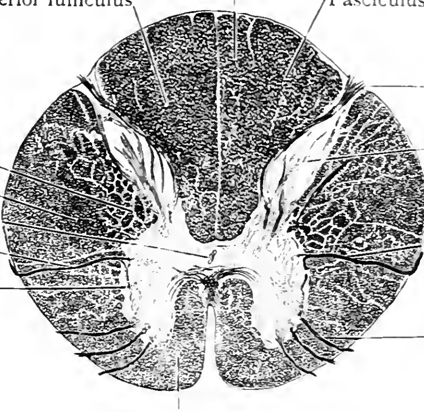

FIG. 26.—Transverse section through the upper part of the Cervical Region of the Medulla Spinalis.

corresponding furrow on the anterior part of each half of the medulla spinalis in connection with the emergence of the fila of the anterior nerve-roots; and it should be noted that the anterior root fila emerge over a relatively broad area, which corresponds in its width to the thickness of the subjacent anterior column of grey matter (Fig. 26).

Grey Matter of the Medulla Spinalis.—The grey matter in the interior of the medulla spinalis has the form of a fluted column. When seen in transverse section, it presents the shape of the letter H. In each half of the medulla spinalis there is a mass of grey matter, comma-shaped in section with the concavity directed laterally. The grey columns of opposite sides are connected across the median plane by a transverse band, which is called the *grey commissure.* The

postero-median septum passes from the surface of the medulla spinalis to the grey commissure. The bottom of the antero-median fissure is separated from the grey commissure by an intervening strip of white matter which is termed the *anterior white commissure.* In the grey commissure may be seen the central canal of the spinal medulla. It is just visible to the naked eye as a minute speck. The canal tunnels the entire length of the spinal medulla, and opens above (after having traversed the lower half of the medulla oblongata) into the fourth ventricle of the brain. The portion of the grey commissure which lies posterior to the central canal is called the *posterior commissure*; the portion anterior to it receives the name of *anterior grey commissure.*

In each lateral mass of grey matter certain well-defined parts may be recognised. The projecting portions which extend posterior and anterior to the connecting transverse grey commissure are termed the *posterior* and the *anterior grey columns.* They can be distinguished from each other at a glance.

The *anterior grey column* is short, thick, and its anterior margin is very blunt. Further, its anterior margin is separated from the surface by a moderately thick coating of white matter, through which the fila of the anterior nerve-roots pass on their way to the surface. The thickened anterior margin of the anterior column is termed its *head*, and the constricted part close to the grey commissure is called the *neck.* The *posterior grey column*, in most localities, is narrow. Further, it is drawn out to a fine edge, which almost reaches the bottom of the postero-lateral sulcus. This sharp edge receives the name of the *apex of the posterior column*; the slightly swollen part which succeeds it is the *head of the posterior column*; whilst the slightly constricted part adjoining the grey commissure goes under the name of the *neck of the posterior column.*

Covering the edge of the posterior column there is a substance which differs in its composition from the general mass of grey matter, and presents a translucent appearance. It is termed the *substantia gelatinosa* (*Rolandi*).

The grey matter is not present in equal quantity throughout the entire length of the medulla spinalis. Therefore it is necessary that it should be considered in different regions; and it must be understood, when the terms cervical, lumbar, sacral, etc. are applied to different portions of the spinal medulla,

that those terms apply to the regions to which the nerves of the same name are attached.

Wherever there is an increase in the size of the nerves attached to a particular part of the medulla spinalis, there a corresponding increase of the grey matter may be noticed. It follows that the districts in which the grey matter bulks most largely are the lumbar and cervical enlargements. The great nerves which go to form the limb plexuses enter and pass out from those portions of the medulla spinalis. In the intervening thoracic region there is a reduction in the quantity of grey matter, in correspondence with the smaller size of the thoracic nerves.

The shape of the columns of grey matter, in section, is not the same in all regions. In the thoracic region both columns are narrow, although the distinction between the anterior grey column and the more attenuated posterior grey column is still sufficiently manifest. In the cervical region the contrast between the grey columns is most marked; the anterior grey column is very thick in comparison with the posterior grey column. In the lumbar region, on the other hand, the difference in the thickness of the two grey columns is not nearly so apparent, owing to a broadening out of the posterior grey column. A section taken from the centre of each region can very readily be recognised by the features mentioned (Fig. 27).

In the thoracic region of the spinal medulla, more especially in the upper part, there is another character which is very distinctive. A pointed and prominent triangular projection juts out from the lateral aspect of the crescentic mass of grey matter, nearly opposite the grey commissure. It is called the *lateral grey column* (Fig. 27, B and C). It disappears in the cervical and lumbar enlargements generally, but again becomes evident both in the upper cervical and in the lower sacral regions.

Below the thoracic region the postero-median septum diminishes and the antero-median fissure increases in depth, until, in the sacral region, they are almost equal in depth and the central canal occupies the centre of the medulla spinalis.

White Matter of the Medulla Spinalis.—The white matter forms a thick coating on the outside of the fluted column of grey matter. It is marked off into three funiculi. The *posterior funiculus* is wedge-shaped in transverse section,

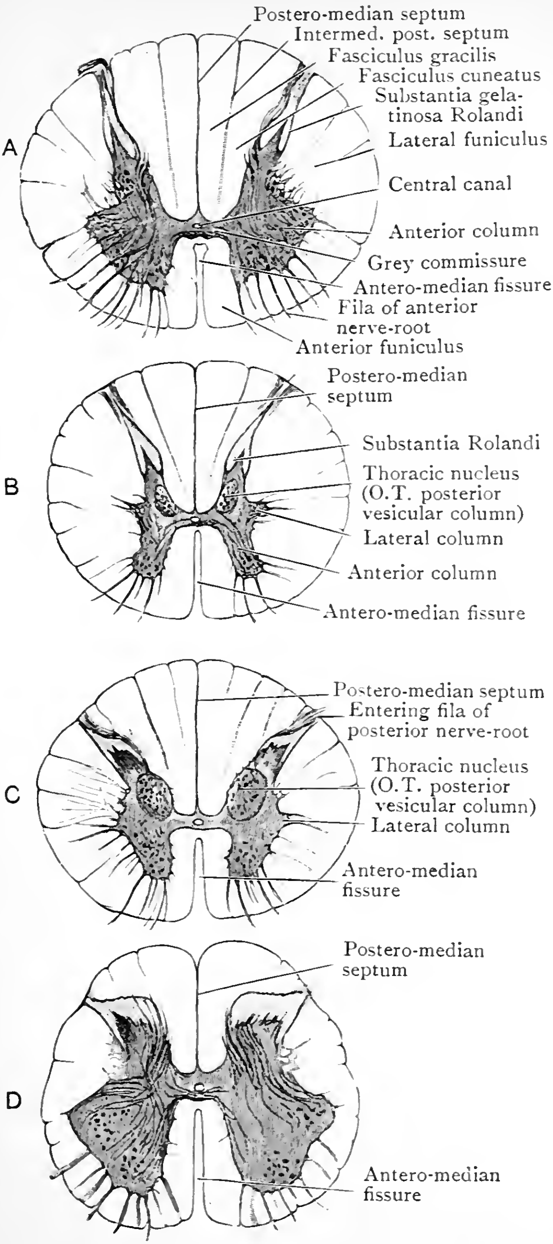

FIG. 27.—Transverse sections through the Medulla Spinalis in different regions. A. Cervical Region; B. Mid-thoracic Region; C. Lower Thoracic Region; D. Lumbar Region.

and lies between the postero-median septum and the posterior grey column. The *lateral funiculus* occupies the concavity of the grey crescent. Posteriorly, it is bounded by the posterior grey column and the postero-lateral sulcus, whilst, anteriorly, it extends as far as the most lateral fila of the anterior nerve-roots. The *anterior funiculus* includes the white matter between the antero-median fissure and the anterior column of grey matter, and also the white matter which separates the thick margin of the anterior grey column from the surface of the spinal medulla and is traversed by the emerging fila of the anterior nerve-roots (Figs. 26, 27).

In the cervical region a faint longitudinal groove runs downwards on the

surface of the posterior funiculus of the medulla spinalis. It indicates the position of a septum which passes into the funiculus from the deep surface of the pia mater and divides it incompletely into two unequal strands. The groove is termed the *intermediate posterior sulcus.* The strand on its medial side is the *fasciculus gracilis* (Goll's), whilst the lateral and larger strand receives the name of the *fasciculus cuneatus* (Burdach's).

The white matter of the medulla spinalis increases steadily in quantity from below upwards.

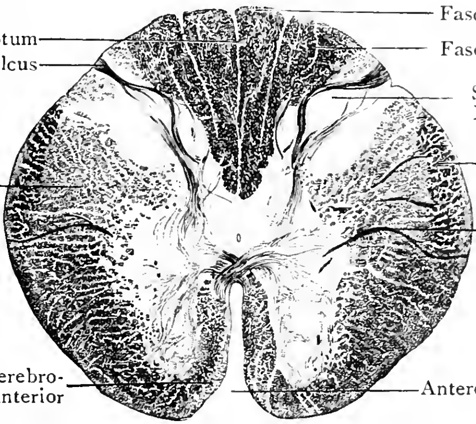

FIG. 28.—Transverse section through the upper cervical part of the Medulla Spinalis of a full-time Fœtus, treated by the Pal-Weigert process.

The fasciculi, gracilis and cuneatus, which form the posterior funiculus of the medulla spinalis, are composed of fibres which enter the spinal medulla as the fila of the posterior nerve-roots. In the lower portion of the medulla spinalis the two fasciculi are not marked off from each other.

In the lateral and anterior funiculi of the adult spinal medulla it is not possible with the naked eye to distinguish the different strands of fibres of which they consist, but the student should remember that such strands or tracts are present. The three best-defined tracts in the antero-lateral part of the spinal medulla are, (1) the fasciculus spino-cerebellaris (O.T. direct cerebellar tract); (2) the fasciculus cerebro-spinalis lateralis (O.T. crossed pyramidal tract); (3) the fasciculus cerebro-spinalis anterior (O.T. direct pyramidal tract).

The *fasciculus spino-cerebellaris* ascends to the cerebellum in the postero-lateral part of the lateral funiculus. Traced in the opposite direction, it is found to disappear in the lower thoracic region of the medulla spinalis. The *fasciculus cerebro-spinalis lateralis* occupies a larger district of the medulla spinalis. It is placed in the lateral funiculus, anterior to the posterior column of grey matter and immediately medial to the fasciculus spino-cerebellaris. As the fasciculus spino-cerebellaris disappears in the lower part of the medulla spinalis the fasciculus cerebro-spinalis lateralis comes to the surface, and it can be traced as low as the fourth sacral nerve. The *fasciculus cerebro-spinalis anterior* forms the narrow strip of the anterior

funiculus which lies immediately adjacent to the antero-median fissure. It reaches down to about the middle of the thoracic region of the medulla spinalis and then disappears.

After the body has been five days on its face it will be replaced upon its back, with the thorax and pelvis supported by blocks; and the dissectors of the head and neck should at once proceed to clean the temporal fascia, and afterwards to remove the brain and study the interior of the cranium.

Dissection.—Take away the anterior and superior auricular muscles and remove the thin layer of fascia subjacent to them which descends from the lower border of the galea aponeurotica to the zygomatic arch. When that has been done the strong temporal fascia will be exposed. Note that it is attached above to the temporal ridge and below to the upper border of the zygomatic arch. The details of its connections will be studied at a later period.

REMOVAL OF THE BRAIN.

After the superficial attachments of the temporal fascia have been noted the dissectors of the head and neck should proceed to remove the brain.

Dissection.—The head being supported upon a block, extend the median incision, already made in the galea aponeurotica, to the nasion anteriorly and to the external occipital protuberance posteriorly, and cut through the loose areolar tissue and the pericranium in the same line down to the bone. With the handle of the scalpel, or with a chisel, detach the pericranium from the bone on each side and turn it downwards to the temporal lines, leaving the bone perfectly bare. Note that although the pericranium is not firmly attached over the surface of the various bones of the vault, it is firmly attached along the lines of the cranial sutures by processes that dip in between the bones and separate their edges. Detach the galea aponeurotica and the temporal fascia from the temporal ridge, on each side, with the edge of the knife; then, carrying the edge of the knife forwards and backwards between the temporal muscle and the bone, detach the upper part of the muscle from the skull. When that has been done, each half of the scalp can be turned down over the ear.

The dissectors should next obtain a saw, a chisel, and a mallet, and proceed to remove the skull cap or calvaria. The line along which the saw is to be used may be marked out on the skull by encircling it with a piece of string, and then marking the cranium with a pencil along the line of the string. Anteriorly, the cut should be made fully three-quarters of an inch above the margins of the orbits; posteriorly, it should be carried round at the level of a point midway between the lambda [1] and the external occipital

[1] The term "lambda" signifies the apex of the occipital bone, or the point at which the sagittal and lambdoidal sutures meet.

protuberance. The saw should be used to divide the outer table of the skull only. When the diploe is reached, the sawdust will become red and moist, and the saw should then be abandoned. The hammer and chisel are now brought into requisition, and by short sharp strokes with these the inner table can readily be split along the line in which the outer table of the cranium is divided. When that has been done, insinuate the hook at the end of the cross-bar of the chisel into the fissure in front, and wrench off the skull-cap.

Dura Mater Encephali.—The brain is clothed by three distinct membranes, which are termed the *meninges*. From without inwards they are—(1) the dura mater; (2) the arachnoid; and (3) the pia mater.

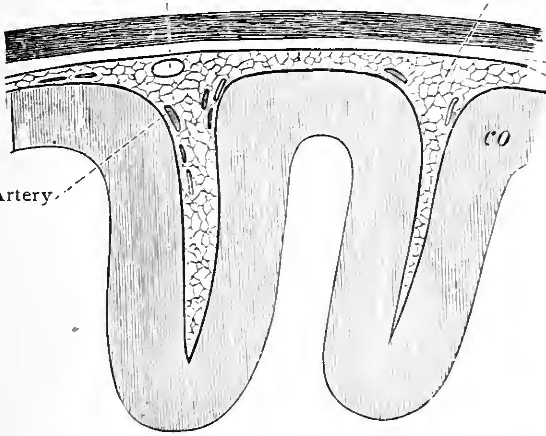

FIG. 29.—Diagrammatic section through the Meninges of the Brain. (Schwalbe.)

co. Grey matter of cerebral gyri.

When the skull-cap is detached, the outer surface of the dura mater, as it covers the upper surface of the cerebral hemispheres, is exposed. It is rough, and dotted over with bleeding points. If a portion is placed in water, its roughness becomes still more manifest, and is seen to be due to a multitude of fine fibrous and vascular processes by which it was connected with the deep surface of the bones. The processes were necessarily torn asunder in the removal of the skull-cap. The bleeding points are most numerous along the median line, or, in other words, along the line of the superior sagittal sinus (O.T. longitudinal); and if the handle of the knife is run from before backwards, so as to make pressure along that line, a considerable quantity of blood will ooze out,

showing that a number of small veins from the cranial bones have been ruptured. The degree of adhesion between the dura mater and the inner surface of the cranial bones varies in different subjects and in different localities. In all cases it is strongly adherent along the lines of the sutures, like the pericranium externally; and, further, it is much more firmly attached to the base than to the vault of the cranium. In the child—indeed, as long as the bones of the cranium are growing—it is more adherent than in the adult; and it is more firmly bound to the bone again in old age.

The dissectors should now clean the outer surface of the dura mater with a sponge. They will then recognise the *middle*

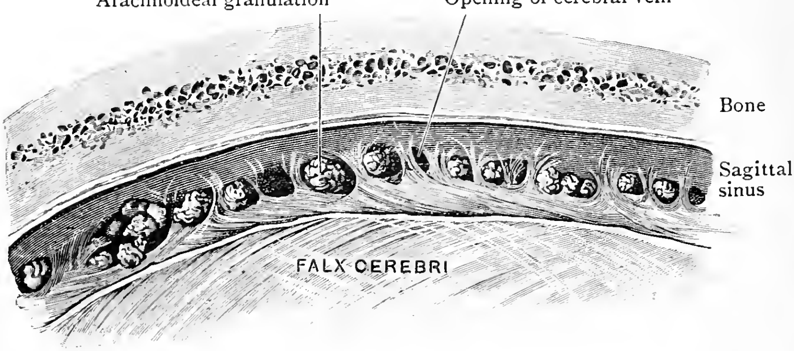

FIG. 30.—Median section through the Frontal Bone and corresponding part of the Superior Sagittal Blood Sinus. The arachnoideal granulations are seen protruding into the sinus. (Enlarged.)

meningeal artery upon each side, ascending in the substance of the outer part of the membrane, and sending off its branches in a widely arborescent manner. It stands out in bold relief from the membrane. If the skull-cap is examined, its inner surface will be observed to be deeply grooved by the artery and its branches, and by the veins which accompany and lie external to them (Wood Jones). The meningeal arteries are not intended for the supply of the membrane alone, as the name might lead one to imagine. They are also the nutrient vessels of the inner table and diploe of the cranial bones (Fig. 32).

Granulationes Arachnoideales (O.T. **Pacchionian Bodies**).—The arachnoideal granulations are almost invariably present, and, as a rule, are best marked in old subjects. They are small granular bodies, ranged in clusters on each side of

the superior sagittal sinus, into which many of them protrude (Fig. 31). As a general rule, they are most evident towards the posterior part of the parietal region. At first sight they appear to be protrusions from the dura mater, but that is not the case. They spring from the arachnoid and the subarachnoid tissue, and are normal enlargements of processes of the arachnoid (Figs. 30, 31).

Two Layers of the Dura Mater.—Having noted the preliminary details from an examination of the outer surface of the dura mater, the student is in a position to understand

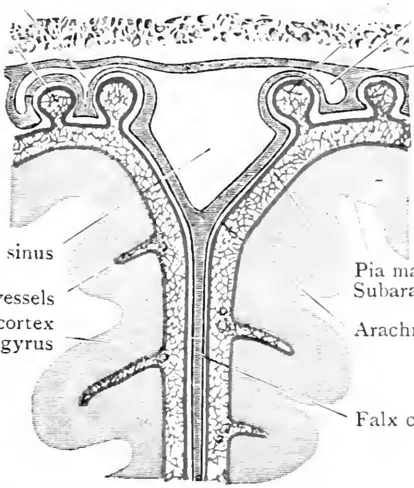

FIG. 31.—Diagram of a frontal section through the middle portion of the cranial vault and subjacent brain to show the membranes of the brain and the arachnoideal granulations.

that the membrane does not belong entirely to the brain. It performs a double function: (1) it acts as an internal periosteum to the bones forming the cranial cavity; and (2) it gives support to the different parts of the brain. Consequently, it consists of two strata, which, in most localities, are firmly adherent, but they can usually be easily demonstrated in the dissecting-room. The two strata may very appropriately be termed the *endocranial* and the *supporting layers.* Along certain lines the two layers separate from each other. In some places they separate to form blood channels, termed *sinuses of the dura mater*, for the passage of venous blood; in other places they separate not only to form blood channels but also

that the inner supporting layer may form strong partitions, which pass in between certain parts of the brain; and by those partitions the cranial cavity is divided into compartments communicating freely with one another, and each holding a definite subdivision of the brain (Figs. 33, 34).

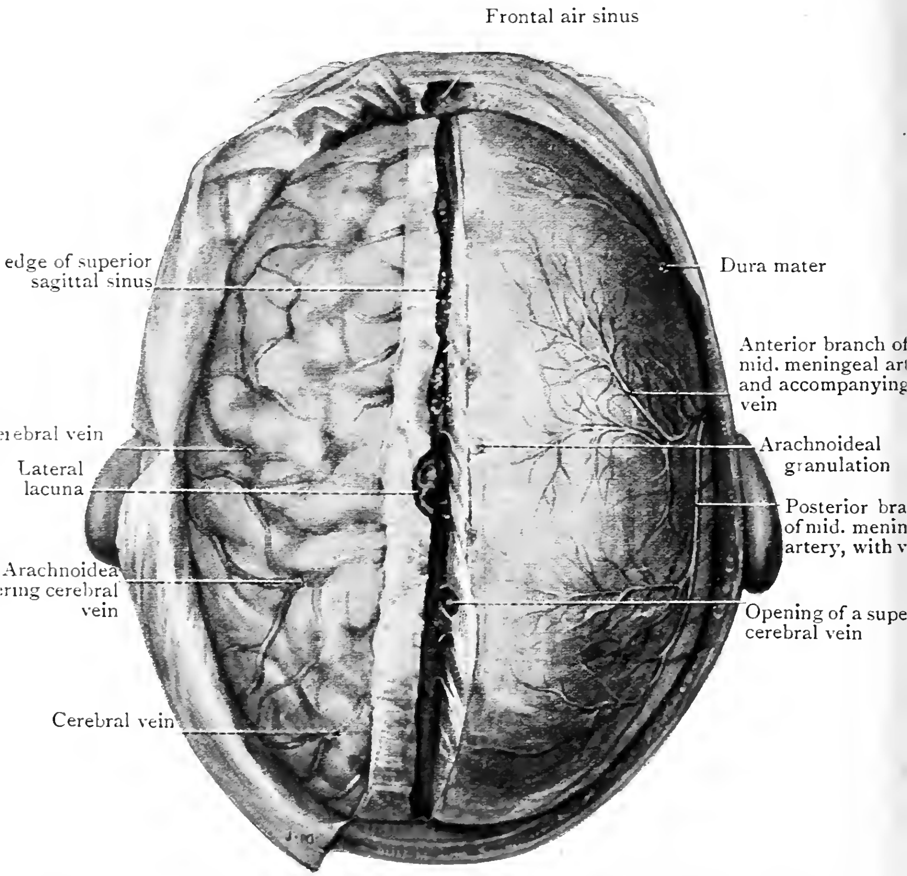

FIG. 32.—Superior Sagittal Sinus; Dura Mater; Middle Meningeal Artery and Vein; Arachnoidea and Superior Cerebral Veins.

Dissection.—The points mentioned must now be verified. Begin by tilting the head forwards. Support it in that position, and make two incisions through the dura mater in an antero-posterior direction—one on each side of the superior sagittal sinus, and along its whole length. From the mid-point of each of the two incisions another cut must be made through the corresponding lateral portion of the dura mater downwards to the cut margin of the skull immediately above the ear (Fig. 32). The dura mater covering the upper aspect of the brain will then be divided into a central strip containing the superior sagittal

sinus, and four triangular flaps. The flaps must be turned downwards over the cut margin of the skull, as on the left side in Fig. 32. In that position they cover the sharp edge of the bone and prevent laceration of the brain during its removal.

Cavum Subdurale.—The term subdural space is applied to the interval between the dura mater and the arachnoid—Figs. 29 and 31. It contains a very small quantity of serous fluid, which moistens the opposed surfaces of the membranes. A striking contrast between the two surfaces of the dura mater will be noted. The external surface is rough and flocculent; the internal surface is smooth and glistening.

Venæ Cerebri.—After the dura mater is reflected, the cerebral veins which return the blood from the surface of the cerebral hemispheres can be seen shining through the arachnoid. They are lodged, for the most part, in the sulci between the gyri of the brain, and those at present visible run upwards to the median plane. When they reach the superior sagittal sinus they turn forwards, and lie against the wall of the sinus, for some distance, before they open into it.

Dissection.—Open into the superior sagittal sinus by running a knife through its upper wall, from behind forwards, Figs. 31 and 32.

Sinus Sagittalis Superior (O.T. **Superior Longitudinal**).—The superior sagittal sinus begins, anteriorly, at the crista galli of the ethmoid bone, where it not infrequently communicates with the veins in the nasal cavity through the foramen cæcum. It extends backwards, grooving the cranial vault in the median plane, to the internal occipital protuberance, on the right aspect of which it becomes continuous with the right transverse sinus (O.T. lateral). Its lumen, which is triangular in cross-section, is very small anteriorly, but expands greatly posteriorly. On each side of the sinus, and opening into it, are a number of clefts between the two layers of the dura mater; they are the *lateral lacunæ*. The inferior angle of the sinus is crossed by a number of minute bands, named *chordæ Willisii*; and arachnoideal granulations bulge into it. The mouths of the superior cerebral veins open into the sinus, or into the lateral lacunæ, pouring their blood into the sinus in a direction contrary to that in which the blood flows within the channel—that is, the terminal portions of the veins are directed forwards, whilst the blood in the sinus flows backwards.

The Relation of the Arachnoideal Granulations to the Superior Sagittal Sinus and the Lateral Lacunæ.—When the granulations project themselves into the sinus or into the lateral lacunæ, they push before them a thin, continuous covering of the floor of the space, and when they project still further and encroach upon the bones of the skull they are covered also by a thin expansion of the roof of the space.

> ***Dissection.***—**In order to expose the *falx cerebri* divide the superior cerebral veins, on each side, and displace the upper parts of the hemispheres of the brain laterally.**

XI. Accessory nerve.
XII. Hypoglossal nerve.

Falx Cerebri (Figs. 33, 34).—The falx cerebri is a sickle-shaped reduplication of the inner layer of the dura mater which descends, in the median plane, between the two cerebral hemispheres. Anteriorly, it is small, and it is attached to the crista galli of the ethmoid bone. As it passes backwards it increases in vertical extent, and the lower border of its posterior portion is attached, in the median plane, to the upper surface of the tentorium cerebelli. The anterior part of the falx is frequently cribriform, and is sometimes perforated by apertures to such an extent that

it almost resembles lace-work. Between its anterior attachment to the crista galli of the ethmoid and its posterior attachment to the tentorium cerebelli its lower margin is free and concave, and it overhangs the corpus callosum, which connects the two hemispheres together, but it is not in contact with the corpus callosum except to a very slight extent posteriorly. Along each border its two layers separate to enclose a blood sinus. Along its upper convex margin runs the *superior sagittal sinus*; along its concave free border

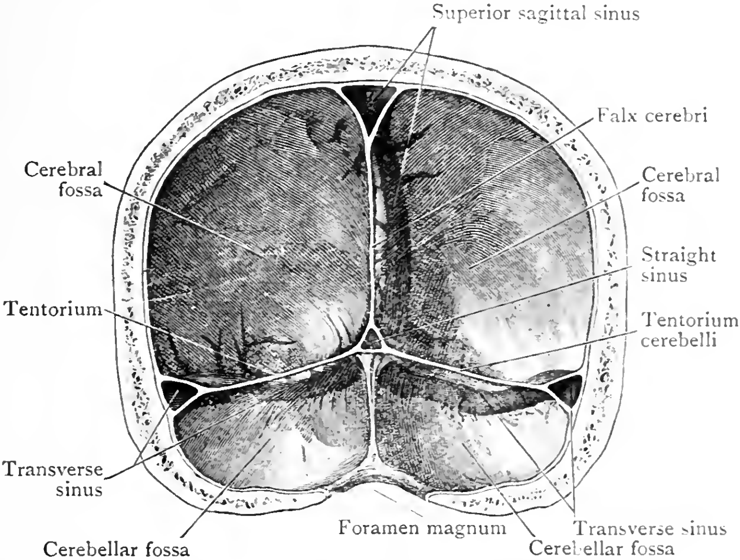

FIG. 34.—Frontal section through the Cranial Cavity in a plane which passes through the posterior part of the foramen magnum. The posterior part of the cranial cavity, from which the brain has been removed, is depicted.

courses the much smaller *inferior sagittal sinus*; whilst along its attachment to the tentorium lies the *straight sinus*.

Dissection.—**Removal of the Brain.[1]—The dissectors should now proceed to remove the brain. Divide the attachment of the falx cerebri to the crista galli and pull the falx backwards. Next, remove the block upon which the head rests, support the occiput and posterior lobes of the brain with the left hand, and let the head drop well downwards. In all probability, the frontal lobes of the brain will fall away, by their own weight, from the anterior fossa of the base of the cranium, and perhaps carry with them the olfactory bulbs. Should they remain in position, however, gently raise them with the fingers, and at the same time separate the olfactory bulbs from the cribriform plate of the ethmoid with**

[1] For alternative method see p. 115.

the handle of the knife. As the olfactory bulbs are raised the minute *olfactory nerves*, which perforate the cribriform plate of the ethmoid bone and pass to the bulbs, will be torn across. The large, round and white *optic nerves* (second pair of cerebral nerves) then come into view, as they pass towards the optic foramina. Divide the optic nerves and the *internal carotid arteries* will be exposed. More posteriorly, in the median plane, the infundibulum will be seen ; it is a hollow conical process which extends from the tuber cinereum, at the base of the brain, to the hypophysis (O.T. pituitary body), which lies in the fossa hypophyseos (O.T. pituitary fossa). Divide the carotid arteries and the infundibulum. Posterior to the infundibulum is the upper border of the dorsum sellæ, terminating on each side in the rounded posterior clinoid process. Passing forwards, on each side of the dorsum sellæ, is the corresponding oculomotor nerve, which must not be touched at present. A little more laterally, and on a slightly lower plane, is the free border of the tentorium cerebelli. The tentorium cerebelli is a fold of the inner layer of the dura mater which lies above the cerebellum and forms the roof of the posterior fossa of the cranium (Figs. 34, 35).

Carefully displace the temporal pole of the brain from under cover of the posterior border of the small wing of the sphenoid, which lies to the lateral side of the optic nerve and the cut end of the internal carotid artery ; then raise the temporal lobe from the floor of the middle fossa, and from the upper surface of the tentorium cerebelli, and note a thick stalk—the midbrain—ascending from the posterior fossa. Push the knife backwards, along the side of the midbrain, immediately above the level of the oculomotor nerve, and cut through the midbrain, from its lateral surface inwards to the median plane, slanting the knife so that it is in the same plane as the surface of the tentorium cerebelli. Repeat the operation in the same way on the opposite side ; then turn the hemispheres backwards, divide the great cerebral vein, immediately behind the cut midbrain, and remove the cerebrum and upper part of the midbrain from the cranium.

Place the removed cerebrum in the vault of the cranium and lay it aside. Then note the relative positions of the parts exposed. Anteriorly lies the floor of the anterior fossa of the cranium ; behind it, on a more depressed plane, the middle fossa, and still more posteriorly the sloping tentorium cerebelli.

In the median plane anteriorly is the projecting crista galli, partially dividing the anterior fossa into halves. On each side of the crista galli is the depression from which the olfactory bulb was dislodged, and still more laterally are the portions of the floor of the anterior fossa which form the roofs of the orbits ; they bulge upwards as well-marked convexities. Each lateral part of the floor of the anterior fossa terminates posteriorly in a sharp margin formed by the posterior border of the small wing of the sphenoid. That margin overhangs the anterior part of the middle fossa. It is covered with a thickening of dura mater in which runs the *spheno-parietal blood sinus*, and it terminates medially in a projecting process, the *anterior clinoid process*. On the medial side of each anterior clinoid process lie the corresponding optic nerve and internal carotid artery, and springing from the upper surface of the artery is its ophthalmic branch, which runs forward under cover of the optic nerve. Posterior

to the divided ends of the internal carotid arteries, and in the median plane, is the infundibulum descending into the hypophyseal fossa, and more posteriorly, one on each side, are the projecting posterior clinoid processes. The area between the four clinoid processes is partially covered by a fold of the inner layer of the dura mater, termed the *diaphragma sellæ*. It binds

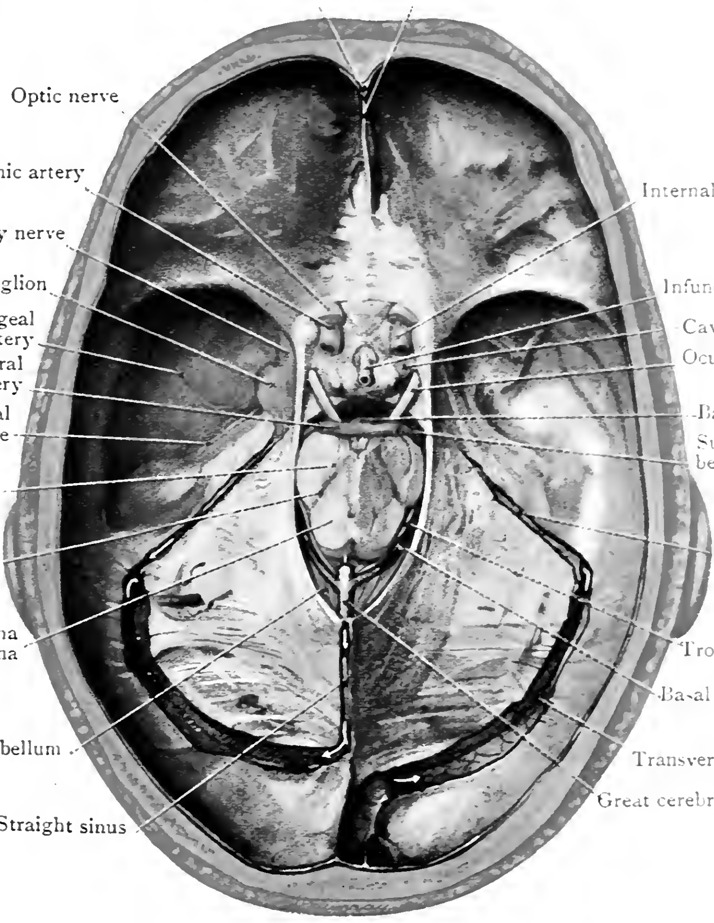

FIG. 35.—Interior of the Cranium after the removal of the cerebrum. The transverse, straight, and superior petrosal sinuses have been opened, and the dura mater has been removed from the floor of the left middle fossa.

down the hypophysis and in its centre is an aperture through which the infundibulum passes to join the hypophysis (O.T. pituitary body), which lies in the hypophyseal fossa in the base of the skull. In the anterior and posterior margins of the diaphragma sellæ are lodged respectively the *sinus intercavernosus anterior* and the *sinus intercavernosus posterior*, which should not be opened at present.

In the dura mater, on each side of the hypophyseal (pituitary) fossa, lies the corresponding cavernous sinus, which will be dissected later, and still more laterally are the depressed lateral portions of the middle cranial fossa, lined with dura mater, in which the trunk and some of the branches of the middle meningeal artery are visible. Posterior to the middle fossa lies the tentorium cerebelli covering the cerebellum. The peripheral margin of the tentorium is attached, on each side, to the posterior clinoid process, the upper margin of the petrous part of the temporal bone, the mastoid angle of the parietal bone, and to the transverse ridge on the inner surface of the occipital bone. The central or free margin crosses the attached margin, behind the posterior clinoid process, on each side, and is attached anteriorly to the apex of the anterior clinoid process. It bounds an oval opening, the door of the tent, through which pass the midbrain, surrounded by the arachnoid and the pia mater, and the posterior cerebral arteries. Traversing the midbrain, nearer its posterior than its anterior border, is a canal called the aquæductus cerebri (O.T. aqueduct of Sylvius). Posterior to the aqueduct is the lamina quadrigemina or tectum of the midbrain, and anterior to it are the right and left pedunculi (O.T. crura) cerebri. Each peduncle consists of an anterior part, *the basis pedunculi* (O.T. *crusta*), and a posterior part, *the tegmentum*, the two being separated by a lamina of dark coloured tissue, *the substantia nigra*. The bases pedunculi are entirely free from each other, but the tegmental portions are united together, anterior to the aqueduct.

Running forwards and laterally from the medial side of each peduncle to the angle between the anterior ends of the free and the attached borders of the tentorium, is the oculomotor nerve. Close to the midbrain the nerve passes between the posterior cerebral artery above and the superior cerebellar artery below; and, between the free and attached borders of the tentorium, it pierces the dura mater, in the middle fossa, and enters the wall of the cavernous sinus. Between the posterior ends of the oculomotor nerves lies the upper end of the basilar artery, dividing into the two posterior cerebral branches; and the dissectors should note that the arteries lie in an enlargement of the subarachnoid space which is known as the *cisterna interpeduncularis*. In the median plane, posterior to the midbrain, is the divided *vena cerebri magna* (O.T. *great vein of Galen*). It passes backwards and upwards, and pierces the apex of the tentorium to enter the straight sinus, which lies in the angle of union between the falx cerebri and the tentorium cerebelli.

Curving backwards around the midbrain and ending posteriorly in the great cerebral vein, on each side, is the *vena basalis*, and immediately above it, running forwards, is the slender trochlear nerve. If the free border of the tentorium is turned laterally, at the point where it is crossing the attached border, the trochlear nerve will be seen perforating the inner layer of the dura mater to enter the wall of the cavernous sinus.

When the dissectors have verified the facts noted above, they should examine the lower, free border of the falx cerebri, in which they will find the small *inferior sagittal sinus*, which terminates posteriorly, at the apex of the tentorium, in the straight sinus. The straight sinus must now be opened by carrying the

knife backwards through the falx cerebri along its line of union with the tentorium. Then the falx cerebri must be cut away from the occipital bone, and as that is done the posterior part of the superior sagittal sinus will be opened up. After the falx has been removed the right and left transverse and the right and left superior petrosal sinuses must be opened by incisions carried along the attached border of the tentorium (Fig. 36). The dissectors will probably find that the superior sagittal sinus turns to the right and becomes continuous with the right transverse sinus, whilst the posterior end of the straight sinus turns to the left and joins the left transverse sinus. In a certain number of cases that arrangement is reversed, and not uncommonly, as in the specimen shown in Fig. 36, there is a communication between the right and left transverse sinuses across the front of the internal occipital protuberance. Occasionally the superior sagittal, the two transverse sinuses, the straight sinus, and the occipital sinus unite, anterior to the internal occipital protuberance, in a common dilatation, the *confluens sinuum* (O.T. torcular Herophili). The transverse sinus, on each side, runs from the internal occipital protuberance to the lateral end of the superior border of the petrous part of the temporal bone, where it dips downwards into the posterior fossa, and at the same point it is joined by the superior petrosal sinus, which runs postero-laterally, along the superior border of the petrous part of the temporal bone, from the cavernous sinus to the transverse sinus, connecting the two together.

With the point of the scalpel open the spheno-parietal sinus, which runs along the posterior border of the small wing of the sphenoid, and trace it medially to the cavernous sinus. Carefully dissect the lateral wall of the cavernous sinus and find in it:—the oculomotor nerve, dividing into two branches; the slender trochlear nerve, crossing the lateral side of the oculomotor; the ophthalmic division of the fifth and its three terminal branches—naso-ciliary, lacrimal, and frontal. Remove the remains of the lateral wall and expose the internal carotid artery and the abducens nerve (p. 234). Then remove the dura mater from the lateral part of the middle fossa on one side to expose the semilunar (O.T. Gasserian) ganglion of the trigeminal nerve; the middle meningeal artery and its two terminal branches; the accessory meningeal artery, if it is present; and the greater superficial petrosal nerve. Commence immediately to the lateral side of the anterior part of the free border of the tentorium, where a cut through the inner layer of the dura will open into a space between the two layers of the dura in which lies the *semilunar ganglion*. From the postero-medial border of the ganglion the *sensory root* passes backwards into the posterior fossa to enter the pons; and from its anterior-lateral border the *ophthalmic branch* passes upwards and forwards in the lateral wall of the cavernous sinus, the *maxillary branch* runs forwards to the foramen rotundum, and the *mandibular branch* passes downwards into the foramen ovale. By the side of the mandibular nerve the accessory meningeal artery may be found entering the cranium; and a little further posteriorly the *middle meningeal artery* will be seen passing into the middle fossa through the foramen spinosum. After entering the cranium the middle meningeal artery runs forwards

and laterally, across the floor of the middle fossa, towards the lateral wall, and divides into an anterior and a posterior branch ; the former ascends on the anterior part of the lateral wall to the anterior inferior angle of the parietal bone, and the latter runs backwards and laterally, and then ascends on the inner surface of the squamous part of the temporal bone. The *greater superficial petrosal nerve* appears on the anterior surface of the petrous part of the temporal bone, through the *hiatus nervi facialis*, which lies to the medial side of an eminence called the *eminentia arcuata*. It runs forwards and medially and disappears beneath the semilunar ganglion (Fig. 36).

When the structures mentioned above have been found and cleaned, the dissectors must remove the tentorium cerebelli. Cut through the free border immediately posterior to the point where it crosses the attached border ; the trochlear nerve will be divided by the incision. Repeat the incision on the opposite side, and then cut through the membrane close to its attached border, but to the medial sides of the superior petrosal and transverse sinuses ; next divide the venæ basales at their points of junction with the vena cerebri magna ; then raise the anterior part of the tentorium and, passing the knife beneath it, separate it from the falx cerebelli, which is attached to its lower surface in the median plane. The tentorium may now be lifted out, and the arachnoid covering the upper surface of the cerebellum will be exposed.

After the upper surface of the cerebellum has been cleaned, cut through the oculomotor nerves, and then press backwards the pedunculi cerebri and the pons (Varolii), which lie immediately below them, to expose the trigeminal and the abducens nerves. Cut the trigeminal nerves as they cross the upper borders of the petrous parts of the temporal bones, and then divide the small abducens nerves, which lie more medially and at a slightly deeper level. Press the pons and cerebellum still further back and divide the facial and acoustic nerves as they enter the internal acoustic meatus. Below the acoustic nerves lie the glossopharyngeal, vagus, and accessory nerves. They also must be cut ; and the roots of the hypoglossal nerves, which lie deeper and more medially, must be identified and divided. The pons can then be displaced still further backwards and the front of the medulla oblongata will be brought into view. Pass the knife downwards, anterior to the medulla oblongata, into the vertebral canal, and, cutting firmly backwards and laterally, on each side, divide the medulla spinalis and the vertebral arteries. Withdraw the knife, pass two fingers downwards, anterior to the medulla oblongata, and lift it and the pons and the cerebellum out of the posterior fossa. Place the lower parts of the brain, which collectively constitute the hind brain, with the hemispheres previously removed, and then examine the cut ends of the cerebral nerves and the blood sinuses which lie in the region of the posterior fossa (Fig. 36).

In the upper end of the vertebral canal lies the upper extremity of the severed medulla spinalis, attached, on each side, to the margin of the foramen magnum by the uppermost dentation of the ligamentum denticulatum. Anterior to the ligamentum denticulatum, on each side, is the vertebral artery, and still more anteriorly, on a slightly deeper plane, the fila of the anterior

root of the first cervical nerve may be distinguished. At a higher level, on each side, the two rootlets of the hypoglossal nerve pierce the dura, as they pass into the hypoglossal canal (O.T. anterior condyloid foramen). The spinal root of the

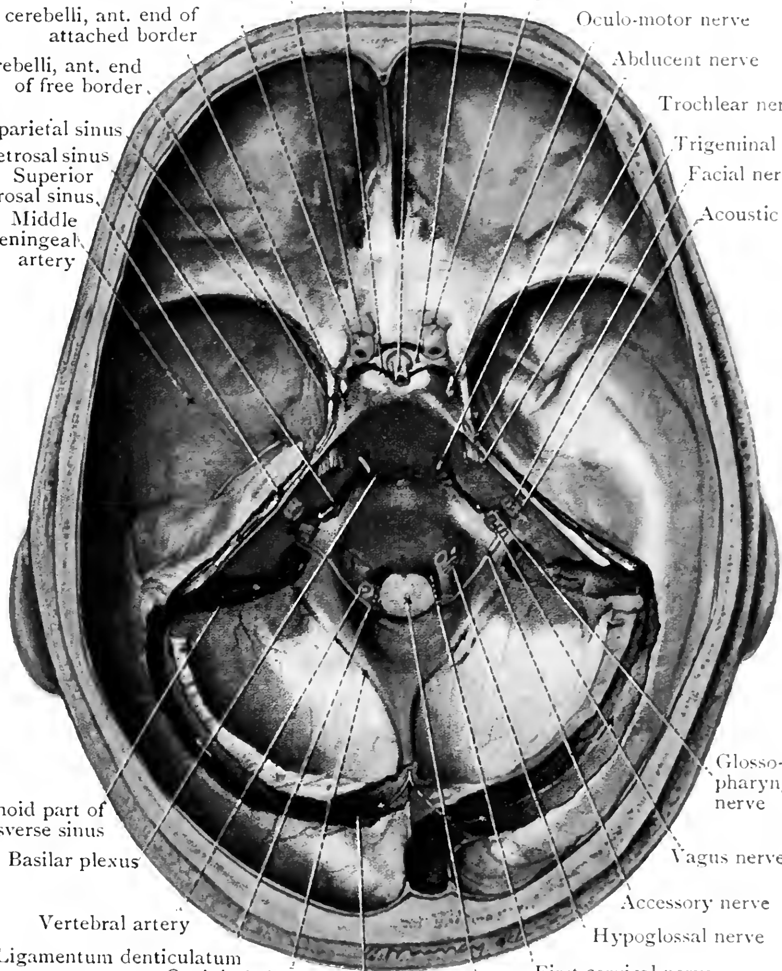

FIG. 36.—Dissection of the Interior of the Cranium after the removal of the brain and the tentorium cerebelli.

accessory nerve passes through the foramen magnum into the cranium, posterior to the ligamentum denticulatum, and, turning laterally over the margin of the foramen magnum, it joins the cerebral fibres of the accessory and the vagus nerves, with which it passes through an aperture in the dura opposite the jugular foramen. Immediately above the accessory and

vagus nerves the smaller trunk of the glossopharyngeal nerve pierces the dura. Above the glossopharyngeal nerve the acoustic nerve and the motor and sensory roots of the facial nerve pass into the internal acoustic meatus, accompanied by the small auditory branch of the basilar artery and the auditory vein. The two roots of the facial nerve lie in a groove on the upper and anterior aspect of the acoustic nerve, the small sensory root (O.T. pars intermedia) being situated between the motor root and the acoustic nerve. The small motor and the large sensory root of the trigeminal nerve pass through an opening in the dura which lies above and medial to the internal acoustic meatus;

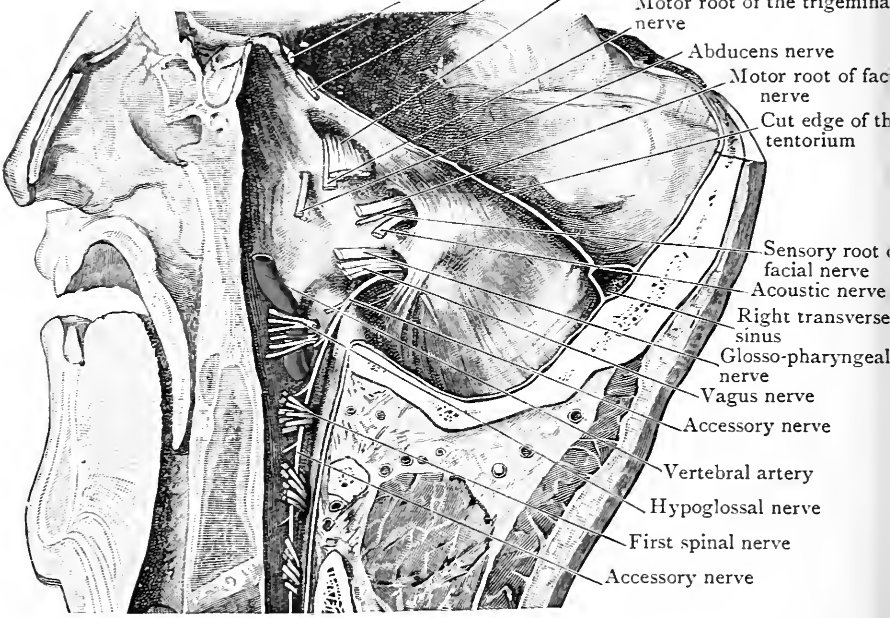

FIG. 37.—Section through the Head a little to the right of the median plane. It shows the posterior cranial fossa and the upper part of the vertebral canal after the removal of the brain and the medulla spinalis.

and the abducens nerve pierces the dura mater below and to the medial side of the opening for the trigeminal nerve, opposite the side of the base of the dorsum sellæ. The small trochlear nerve pierces the inferior surface of the free border of the tentorium at the point where it is crossing the attached border.

After the dissectors have familiarised themselves with the positions of the cerebral nerves as they pierce the dura mater, they should examine the falx cerebelli and complete the display of the cranial blood sinuses.

Falx Cerebelli.—The falx cerebelli is a small sagittal fold

of the inner layer of the dura mater which projects forwards, between the lateral lobes of the cerebellum, from the internal occipital crest (Figs. 33, 34).

Sinus Transversus (O.T. **Lateral**).—The horizontal part of the transverse sinus has already been traced from the internal occipital protuberance to the superior border of the petrous part of the temporal bone, where it turns downwards to the jugular foramen. At first the descending portion runs downwards, on the inner surface of the mastoid part of the temporal bone, and then forwards and again downwards across the upper and anterior surfaces of the jugular process of the occipital bone. On account of the sinuosity of its course this part is called the *sigmoid portion of the transverse sinus* (Fig. 36).

Dissection.—Open the sigmoid part of the sinus and find the mouth of the mastoid emissary vein in its posterior border, about half-way down.

The dissectors should now obtain the basal part of a macerated skull and should note the relation of the transverse sinus to the outer surface. They will find that the position of the sinus can be indicated on the external surface, by a line which commences at the external occipital protuberance, passes forwards, with a slight upward convexity, along the superior nuchal line to the upper part of the mastoid part of the temporal bone and then descends to the level of the lower margin of the external meatus (Figs. 38, 204).

Sinus Occipitalis.—The occipital sinus is not uncommonly absent. When it is present it commences in the right or left transverse sinus or the confluens sinuum, and descends for a short distance in the posterior border of the falx cerebelli. It terminates below in two branches, which leave the falx cerebelli and run along the borders of the foramen magnum, between the layers of the dura mater, to terminate anteriorly in the lower ends of the transverse sinuses.

Sinus Petrosus Inferior.—The inferior petrosal sinus lies along the posterior border of the petrous part of the temporal bone, extending from a point lateral to the opening for the abducens nerve to the medial side of the opening in the dura for the glossopharyngeal nerve of the same side. Lay the sinus open. It opens anteriorly into the cavernous sinus, from which it receives blood, and posteriorly it passes through

the jugular foramen to join the upper end of the internal jugular vein.

Plexus Basilaris.—The two inferior petrosal sinuses are connected together, across the upper surface of the basilar part of the occipital bone, by a plexus of small venous channels, to which the term basilar plexus is applied. Unless the channels happen to be distended with blood the dissectors will probably be unable to display the plexus (Fig. 36).

The dissectors should note that the dura mater is much more firmly attached to the bones of the base than it was to the bones of the vertex, a fact which should have attracted their attention as they removed the membrane from the floor of the middle fossa. They should note also that it gives sheaths to the nerves which pierce it, and that at the margins of the various foramina its outer layer becomes continuous with the periosteum on the outer surface of the cranium, whilst at the margin of the foramen magnum the inner layer becomes continuous with the single layer of dura mater which surrounds the medulla spinalis ; and that, at the same level, the arachnoid and pia mater of the brain become continuous with the arachnoid and pia mater of the spinal medulla (O.T. spinal cord). Before terminating the survey of the interior of the cranium, the dissectors should revise their knowledge of the blood vessels, and their relations to the dura mater ; and they should remove the hypophysis (O.T. pituitary body) and investigate its naked-eye structure.

Sinus Duræ Matris.—*Four blood sinuses lie in the median plane*: (1) the superior sagittal sinus, in the upper or attached border of the falx cerebri ; (2) the inferior sagittal sinus, in the free part of the lower border of the falx cerebri ; (3) the straight sinus, along the line of attachment of the falx cerebri with the tentorium cerebelli ; (4) the occipital sinus, in the upper part of the attached border of the falx cerebelli.

Two sinuses lie in a higher horizontal plane: they are the spheno-parietal sinuses, which run along the posterior borders of the small wings of the sphenoid bone.

Six sinuses lie in a lower horizontal plane: (1) the two cavernous sinuses, at the sides of the body of the sphenoid ; (2) the two superior petrosal sinuses, along the upper borders of the petrous parts of the temporal bones, in the anterior parts of the attached border of the tentorium cerebelli ; (3) the horizontal parts of the transverse sinuses, in the posterior

parts of the attached border of the tentorium. The terminal parts of the transverse sinuses descend along the anterior parts of the lateral walls of the posterior fossa.

Two sinuses run obliquely downwards, backwards, and laterally: they are the two inferior petrosal sinuses.

Three sinuses run transversely, connecting paired sinuses of opposite sides: (1) the anterior intercavernous sinus, in the anterior border of the diaphragma sellæ; (2) the posterior intercavernous sinus, in the posterior border of the diaphragma sellæ; and (3) the basilar plexus, which connects together the inferior petrosal sinuses, across the upper surface of the basilar part of the occipital bone.

Alternative Method of removing the Brain.—If it is thought desirable to remove the brain entire, by the more rapid but less instructive method usually adopted in the post-mortem room, then the following steps should be taken after the falx cerebri has been detached from the crista galli and the dura mater lining the vault of the cranium has been thrown aside (see p. 105).

Remove the block upon which the head has been resting, supporting the occiput and the posterior part of the brain with the left hand, and let the head drop well downwards, and, in all probability, the weight of the frontal lobes will draw them away from the floor of the anterior fossa of the skull, and possibly the *olfactory bulbs* may be carried with them. If the olfactory bulbs remain in position on the cribriform plates of the ethmoid at the sides of the crista galli, gently raise them with the handle of the scalpel and press them backwards on to the lower surfaces of the frontal lobes. As the olfactory bulbs are raised the *olfactory nerve filaments*, which enter their lower surfaces after passing through the cribriform plates, are torn. As the frontal lobes are pressed backwards, the large, round and white *optic nerves* come into view, as they are approaching the optic foramina. When they are divided the *internal carotid arteries* will be exposed. More posteriorly, in the median plane, lies the *infundibulum*, a hollow conical process which connects the *hypophysis cerebri* (O.T. *pituitary body*) with the *tuber cinereum* at the base of the brain; and more laterally are the *oculomotor nerves*. Sever each of the structures mentioned in turn. On the lateral side of each oculo-motor nerve lies the medial or free border of the tentorium cerebelli, passing forwards to be attached to the anterior clinoid process. Turn that margin aside with the point of the knife, and the small *trochlear nerve* (fourth cerebral nerve) will be brought into view. It lies under shelter of the free border of the tentorium, and should be divided at this stage. The head must in the next place be turned forcibly round, so that the face is directed over the left shoulder. Raise the posterior part of the right cerebral hemisphere with the fingers, and note that it rests upon the tentorium cerebelli—a broad sloping process of dura mater which intervenes between it and the cerebellum. Divide the tentorium along its attached border, and take care whilst doing that not to injure the sub-

jacent cerebellum. Next turn the head so as to bring its left side uppermost, and treat the tentorium on that side in the same manner. Now let the brain fall well backwards ; then the pons and medulla will be drawn away from the anterior wall of the posterior fossa of the skull, and the nerves in the posterior fossa will come into view. They are the two parts of the *trigeminal nerve* (fifth cerebral nerve), perforating the dura mater near the apex of the petrous portion of the temporal bone ; the *abducent nerve* (sixth cerebral nerve), piercing the dura mater behind the dorsum sellæ of the sphenoid bone ; the *facial nerve* and the *acoustic nerve*, disappearing into the internal acoustic meatus ; the *glossopharyngeal*, the *vagus*, and the *accessory nerves*, leaving the skull through the jugular foramen ; and the two slips of the *hypoglossal nerve*, piercing the dura mater over the hypoglossal canal (O.T. anterior condyloid foramen). Each in turn will be displayed upon each side. They must be divided in the order mentioned, except that, in the case of the nerves passing out of the cranium through the jugular foramina, the dissector should endeavour to leave the accessory of the right side intact within the cranium, by dividing its roots of origin from the medulla oblongata, whilst on the other side he should remove it with the brain. The accessory nerve is readily recognised because its spinal part ascends from the vertebral canal into the cranial cavity through the foramen magnum. Now, thrust the knife into the vertebral canal, and divide the medulla spinalis and the vertebral arteries, as they turn forwards upon the upper part of the medulla spinalis (O.T. spinal cord) ; then sever the accessory nerve of the left side, and the roots of the first pair of spinal nerves. When that has been done let the head fall well downwards, gently dislodge the medulla oblongata and cerebellum, and the whole brain can be removed. The vena cerebri magna (Galen), as it passes from the interior of the brain to enter the straight sinus, is ruptured as the brain is removed. The dissector should now return to p. 112, and should study the positions and relations of the cranial blood sinuses.

Meningeal Veins.—In addition to the named blood sinuses, venous channels accompany the meningeal arteries, and more particularly the trunks and branches of the middle meningeal artery. The meningeal veins are of wider calibre than the corresponding arteries, and lie external to them, in the grooves on the inner surfaces of the cranial bones. When the arteries are distended they compress the middle parts of the veins and drive the blood into their anterior and posterior margins. When that occurs each artery appears to be accompanied by two veins, a circumstance which is probably responsible for the statement that some of the meningeal arteries have venæ comites.

Emissaria.—Emissary veins are blood channels which connect the sinuses of the dura mater with the veins which lie outside the cranium. They are: (1) Emissary veins connected with the superior sagittal sinus—(*a*) from the anterior extremity of the sinus an emissary vein passes through the foramen cæcum ; this vein divides below, and either

PLATE III

FIG. 39.—Radiograph of Skull of a Child—lateral view—showing the relation of the internal carotid artery to the base of the skull. The portion of the artery shown was injected. (Dr. H. M. Traquair.)

becomes continuous with the veins of the nasal fossæ, or its branches pass through foramina in the nasal bones and join the angular veins; (*b*) two parietal emissary veins, which pass through the parietal foramina and connect the superior sagittal sinus with the occipital veins. (2) Emissary veins connected with the transverse sinuses—(*a*) two mastoid emissary veins, one on each side, pass through the mastoid foramina and connect the sigmoid parts of the transverse sinuses with the posterior auricular veins; (*b*) two posterior condyloid veins, one on each side, pass through the condyloid canals and connect the lower ends of the transverse sinuses with the plexuses of veins in the sub-occipital triangles. One or both of the posterior condyloid veins may be absent. (3) Emissary veins connected with the cavernous sinuses—(*a*) a vein which traverses the foramen ovale, or the foramen Vesalii, and connects the cavernous sinus with the plexus of veins around the external pterygoid muscle; (*b*) a plexus of veins which passes through the temporal bone with the internal carotid artery, and connects the cavernous sinus with the pharyngeal venous plexus; (*c*) in a sense, the ophthalmic vein may be considered an emissary vein, for, although under ordinary circumstances it is a tributary of the sinus, blood can flow through it, in the opposite direction, from the sinus into the orbit, and then along the tributaries which connect the ophthalmic vein with the angular vein, and along the channels which connect the ophthalmic vein, through the inferior orbital fissure, with the veins in the infratemporal region.

The Arteries of the Cranial Cavity.—(1) *The vertebral arteries*; (2) *the internal carotid arteries*; (3) *the meningeal arteries.*

Arteriæ Vertebrales.—The vertebral arteries, right and left, pierce the spinal dura mater below the foramen magnum, through which they enter the cranium. As each artery passes through the foramen it lies anterior to the highest dentation of the ligamentum denticulatum, and it passes between the hypoglossal and first cervical nerves. It was divided when the hind brain was removed, and its cut extremity lies near its point of entrance into the cranial cavity (Figs. 36, 37).

Arteriæ Carotides Internæ.—Each internal carotid artery enters the cranium at the foramen lacerum, between the apex of the petrous part of the temporal bone and the body of the sphenoid, where it pierces the outer layer of the dura mater.

Then it runs forwards, in the cavernous sinus, to the medial side of the anterior clinoid process, where it turns upwards, pierces the inner layer of the dura mater and the arachnoid, and gives off its ophthalmic branch, which runs forwards below the optic nerve into the orbit. The artery was cut immediately behind its ophthalmic branch during the early stages of the removal of the brain (Figs. 36, 39).

Meningeal Arteries.—The meningeal arteries are the nutrient arteries of the dura mater, and of the inner table and diploe of the cranial bones. They are derived from a great number of different sources, but the only one of any size is the *middle meningeal branch* of the internal maxillary artery. The others are small twigs, and, except in a well-injected subject, will not be easily made out. They are: (1) *anterior meningeal*, from the anterior ethmoidal artery; (2) a meningeal branch of the lacrimal artery; (3) the *accessory meningeal*, from the internal maxillary artery; (4) some small branches from the ascending pharyngeal, occipital, and vertebral arteries.

Each *middle meningeal artery* is a branch of the corresponding internal maxillary artery. It enters the cranium through the foramen spinosum of the sphenoid bone, and divides, upon the inner surface of the great wing of that bone, into two large terminal branches. The anterior of the two branches ascends upon the great wing of the sphenoid, and upon the anterior inferior angle of the parietal bone, grooving both deeply, whilst the posterior branch turns backwards and upwards upon the squamous portion of the temporal bone. The branches which proceed from the two main divisions spread out widely and, with the accompanying venous channels, occupy the arborescent grooves on the inner surface of the cranial vault (Fig. 204).

The vein which accompanies the middle meningeal artery passes through the foramen spinosum and ends in the plexus around the external pterygoid muscle.

Each *anterior meningeal artery* proceeds from the anterior ethmoidal artery as it accompanies the anterior ethmoidal nerve across the cribriform plate of the ethmoid bone. It supplies a limited area of dura mater and bone in the anterior fossa of the cranium.

The *meningeal branch of the lacrimal artery* enters the middle cranial fossa through the superior orbital fissure, and

it anastomoses with the rami of the anterior division of the middle meningeal artery.

The *accessory meningeal artery* (O.T. *small meningeal*) is somewhat inconstant; it arises either directly from the internal maxillary or from the middle meningeal, and enters the cranium through the corresponding foramen ovale, but it should not be looked for at the present stage, as it is best examined along with the semilunar (O.T. Gasserian) ganglion and the three divisions of the trigeminal nerve.

The *meningeal branches from the ascending pharyngeal arteries* are the terminal twigs of those vessels. They enter the cranium through the lacerate and jugular foramina, and

a'. Infundibulum, with projection from anterior lobe upwards anterior to it.

through the hypoglossal canal (O.T. anterior condyloid foramen). The branch which passes through the jugular foramen is the largest.

The *meningeal branches of the occipital and vertebral arteries* are small, and are distributed in the posterior cranial fossa. The former enter through the jugular, mastoid, and parietal foramina, the latter through the foramen magnum.

The *meningeal veins* may be regarded as being arranged in two sets: one set consists of small channels which pour their blood into the blood sinuses; the other set is composed of veins which accompany the meningeal arteries and carry their blood to venous trunks on the exterior of the cranium.

Dissection.—Cut away the overhanging margins of the diaphragma sellæ and carefully dislodge the hypophysis from the fossa hypophyseos (pituitary fossa) of the sphenoid bone; then,

with a chisel chip away the floor of the hypophyseal fossa and open up the sphenoidal air sinuses—right and left—which lie in the body of the sphenoid bone below the fossa. They are generally of unequal size and may be replaced in some cases by a single cavity. Attempt to pass a probe through the aperture in the anterior wall of each sinus into the corresponding section of the nasal cavity (Fig. 110).

Hypophysis Cerebri (O.T. **Pituitary Body**) (Fig. 40).—The hypophysis is an oval structure, slightly flattened from above downwards, and with its long axis placed transversely. It consists of a large anterior lobe, and a smaller posterior lobe. The anterior lobe is hollowed out posteriorly so as to form a concavity for the lodgment of the posterior lobe. If a sagittal section is made through the hypophysis, the line of separation between the two lobes is seen very distinctly. The infundibulum, which connects the hypophysis with the tuber cinereum of the brain, is attached to the posterior lobe only (Fig. 40, 1). Thus, even in the adult, there is a clue to the different modes of development of the two lobes. The posterior lobe is derived from the brain, whilst the anterior lobe is an off-shoot from the primitive buccal cavity.

When the inspection of the interior of the cranium is completed the dissectors must fill the cranial cavity with tow steeped in preservative solution; replace the skull-cap in position and retain it by bringing the scalp flaps over it, and stitching them accurately together. The brain must be put in a jar in a 5 per cent solution of formalin and placed aside till the dissection of the remaining parts of the head and neck is finished.

THE ANTERIOR PART OF THE NECK.

After the skull-cap has been replaced and the scalp has been stitched over it, let the head hang down over the end of the table, pull the chin as far from the sternum as possible and fix it in position with hooks. Then examine the region of the front of the neck. It is a large triangular area, bounded laterally by the anterior borders of the sterno-mastoid muscles, above by the lower border of the mandible, and below by the middle part of the upper border of the manubrium sterni; and it is divided by the median plane into two smaller subsidiary triangles, *the anterior triangles of the neck*, each of which is bounded above by the mandible, behind by the sterno-mastoid, and in front by the middle line of the neck. Pass the index finger from the chin to the sternum along the

PLATE IV

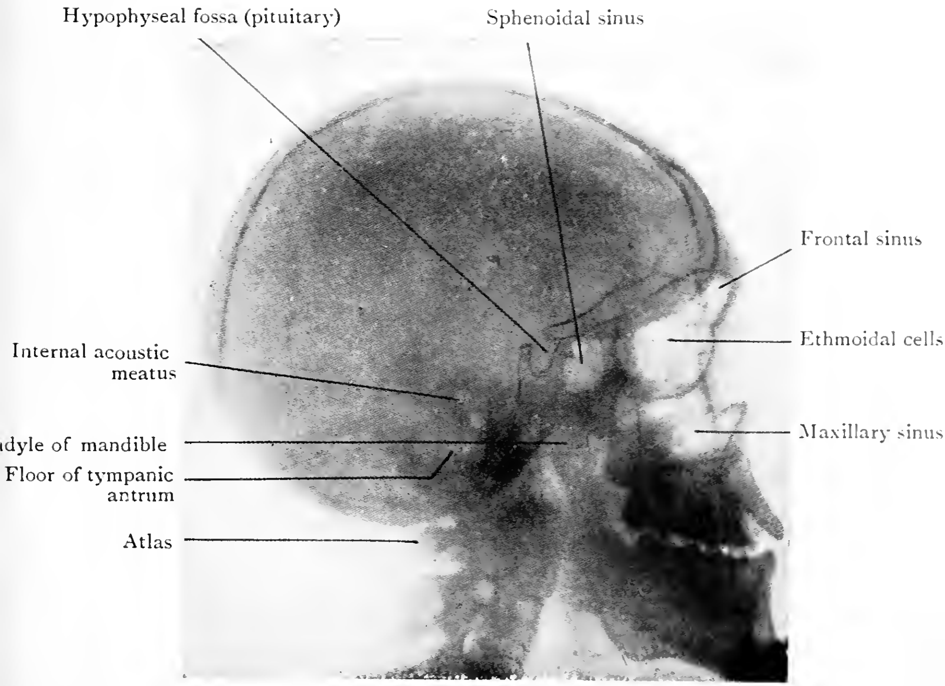

FIG. 41.—Lateral radiograph of a living Skull. (Gouldesbrough.)

PLATE V

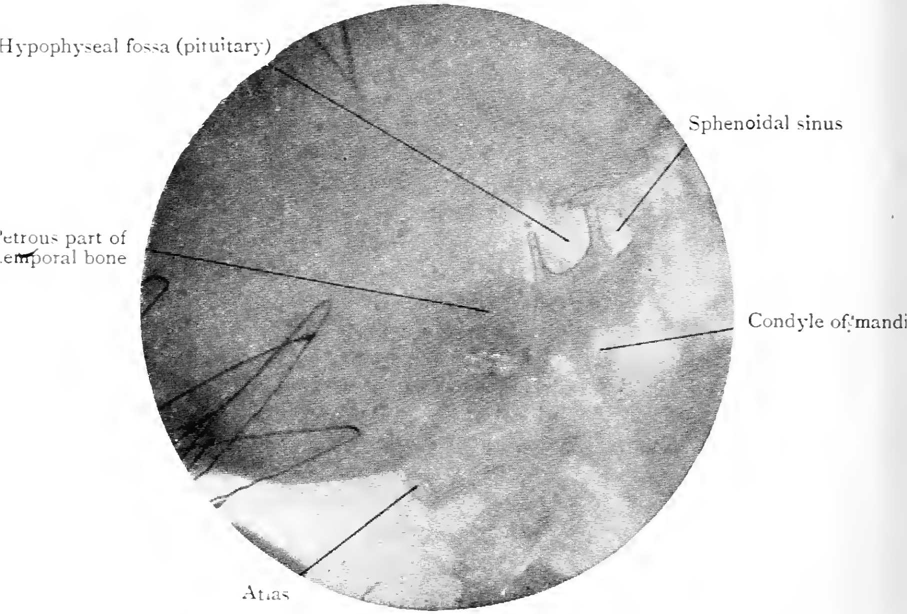

FIG. 42.—Lateral view of Skull showing hypophyseal fossa and sphenoidal sinus. (Gouldesbrough.)

median line and locate in sequence the body of the hyoid bone, the angular anterior border of the thyreoid cartilage, the rounded arch of the cricoid cartilage and the rings of the trachea. The latter are partly masked by the isthmus of the thyreoid gland. Place the thumb and the forefinger on the body of the hyoid bone and carry them backwards, one on each side, along its greater cornua. Note that the posterior ends of the cornua lie immediately in front of the anterior borders of the sterno-mastoid muscles. Above the body of the hyoid bone lies the *submental triangle* bounded superiorly by the mylo-hyoid muscles, which form the diaphragm of the mouth; and above each greater cornu is the corresponding *submaxillary region*. Between the body of the hyoid bone and the upper margin of the thyreoid cartilage is the thyreo-hyoid space, bounded posteriorly by the middle part of the thyreo-hyoid membrane, which lies anterior to the upper part of the pharynx and the middle of the epiglottis (Fig. 110). Trace the upper border of the thyreoid cartilage backwards and note that it terminates, on each side, in a pointed projection, the superior cornu, which lies immediately in front of the anterior border of the sterno-mastoid. Between the lower margin of the thyreoid cartilage and the upper border of the cricoid cartilage lies the cricothyreoid ligament, forming part of the anterior wall of the lower portion of the larynx.

The dissectors should make themselves thoroughly familiar with the landmarks mentioned above, both on their own necks and on the necks of their friends, and they should note that, whilst in the dead subject there may be some difficulty in palpating the isthmus of the thyreoid gland, as it crosses anterior to the second, third and fourth rings of the trachea, they will have no difficulty in locating the small soft cushion-like mass in the living subject.

Dissection.—The skin was cut along the lower border of the mandible at the commencement of the dissection of the face; now, make a median incision through it, from the chin to the sternum, and turn the triangular flap, thus marked out, backwards and laterally, to a short distance beyond the anterior margin of the sterno-mastoid. When that is done the superficial fascia covering the anterior triangle on each side will be exposed; it is thickest and most laden with fat in the submental region. In the upper and posterior part of it lie the fibres of the platysma, running upwards and forwards towards the mandible. Some of the anterior fibres of the muscle gain attachment to the anterior part of the lower border of the mandible, and some

decussate with their fellows of the opposite side beneath the chin. The posterior fibres ascend into the face, where they have already been followed to their connection with the risorius and the orbicularis oris (p. 7). Cut through the platysma along the anterior border of the sterno-mastoid and turn it upwards, dividing the twigs of the cervical branch of the facial nerve which supply it. Secure the two terminal branches of the *nervus cutaneus colli* (O.T. transverse cervical nerve), crossing the middle of the sterno-mastoid; trace its two branches forwards, and note the union between the upper branch and the cervical branch of the facial nerve, which was found passing downwards and forwards behind the angle of the mandible in a previous dissection (see p. 15). In the superficial fascia of the submental region and the anterior part of the submaxillary region secure the tributaries of the anterior jugular vein; trace them downwards to the trunk of the vein, and follow the trunk to the point where it pierces the deep fascia; then remove the superficial fascia and expose the deep fascia of the anterior region. Note that the deep fascia extends in a continuous layer from the mandible to the sternum and from the sterno-mastoid of one side to that of the other side. Note, further, that it is attached to the body and the greater cornua of the hyoid bone. The latter attachment separates the infra-hyoid muscles, which lie in the lower part of the neck, from the supra-hyoid muscles, which are situated in the region of the floor of the mouth.

The dissectors will remember that in the course of the dissection of the posterior triangle they met with several layers of the deep fascia. A similar division into layers exists in the anterior region, and the opportunity should be taken, whilst the fascia is still uninjured, to demonstrate certain of the layers and the presence of the spaces between them.

The Suprasternal Space.—Make a transverse incision through the deep fascia, immediately above the sternum, and two vertical incisions, one along the anterior border of each sterno-mastoid muscle. Carry the latter incisions upwards for about 38 mm. (one and a half inches), and turn the flap of fascia marked out upwards. The space opened into by the reflection of the first layer of deep fascia of the lower part of the neck is the *suprasternal space* (Burns). Remove the areolar tissue which fills it, find the lower parts of the anterior jugular veins and the transverse anastomosis between them, and expose the second layer of deep fascia, which forms the posterior boundary of the space and covers and binds together the infrahyoid muscles of opposite sides. Pass the handle of the scalpel downwards along the posterior wall of the space, and note that it terminates, a short distance below the upper border of the sternum, where the second layer of fascia is attached to the posterior surface of the manubrium, immediately above the origins of the infra-hyoid muscles. If the handle of the knife is passed laterally, along the posterior wall of the space, it will pass deep to the sterno-mastoid into the posterior triangle (see p. 34), and if it is pushed upwards it will be stopped by the union of the first and second layers of the deep fascia, about half-way between the sternum and the thyreoid cartilage. The attachments of the second layer of deep fascia of the lower part of the neck may be summarised as follows. It is attached,

below, to the posterior surface of the manubrium sterni and to the posterior border of the clavicle, to which it binds the posterior belly of the omo-hyoid (p. 34). Above, it fuses with the more superficial layer, along an oblique line which ascends from the level of the coracoid process to the level of the upper end of the trachea. Above that level it forms, with the superficial layer, a common lamella, which ascends on the infra-hyoid muscles to gain attachment to the body and greater cornu of the hyoid bone. The space between the two layers contains, in the region of the anterior triangle, the lower parts of the anterior jugular veins, the anastomosis between them, and the areolar tissue in which they are embedded. In the posterior triangle its contents are the lower end of the external jugular vein, the terminations of the transverse cervical and transverse scapular veins, the transverse scapular artery, and areolar tissue. Note that the *anterior jugular vein*, on each side, arises in the superficial fascia of the submental region and descends superficial to the deep fascia in the upper part of the neck; then it pierces the first layer of deep fascia and lies between the two layers, where it anastomoses with its fellow of the opposite side; finally, it turns laterally, deep to the sterno-mastoid, and terminates in the external jugular vein at the anterior boundary of the subclavian part of the posterior triangle.

Make two incisions through the deep fascia of the upper part of the anterior triangle, one along the lower border of the mandible, from the angle to a point 12.5 mm. (half an inch) from the chin, and a second at right angles to the first, from its middle to the greater cornu of the hyoid bone. Whilst making the horizontal incision avoid injuring the *external maxillary artery* (O.T. facial) and the *anterior facial vein*, which pierce the deep fascia at the level of the anterior border of the masseter. Reflect the two triangular flaps of fascia marked out by the incisions, and expose the lower surface of the *submaxillary salivary gland*, the *submaxillary lymph glands*, the *anterior* and *posterior bellies of the digastric muscle*, the lower part of the *stylo-hyoid muscle*, and a further part of the anterior facial vein.

The majority of the submaxillary lymph glands lie along the lower border of the mandible, on the superficial surface of the submaxillary gland. The anterior facial vein crosses the posterior part of the submaxillary gland superficially. The external maxillary artery dips deeply between the lower border of the mandible and the submaxillary gland. The posterior and lower part of the submaxillary gland usually overlaps the stylo-hyoid and the posterior belly of the digastric muscles, and not infrequently it overlaps the greater cornu of the hyoid bone also. Its anterior border may overlap the anterior belly of the digastric. Raise the lower border of the gland and expose another layer of deep fascia covering the muscles which lie deep to the gland. Place the handle of the knife on that fascia and push it gently upwards. Note that it passes upwards to the level of the mylo-hyoid line on the medial surface of the mandible, to which the mylo-hyoid muscle is attached. The fascial sheath in which the submaxillary gland is enclosed consists, therefore, of a superficial layer of deep fascia which extends from the greater cornu of the hyoid bone to the lower border of the mandible, and a deeper layer which passes from the greater cornu of the

hyoid to the mylo-hyoid line of the mandible. In front of the anterior belly of the digastric, the two layers blend with the single layer of deep fascia which covers the lower surfaces of the mylo-hyoid muscles. Behind the posterior belly of the digastric they unite with the connective tissue in which the carotid vessels are embedded.

When the details of the deep fascia have been examined, the sterno-mastoid should be studied.

M. Sternocleidomastoideus.—The sterno-mastoid muscle lies between the anterior and posterior triangles of the neck (Fig. 43). It is attached, below, by two heads—a sternal and a clavicular. The sternal head is rounded, and chiefly tendinous; it springs from the upper part of the anterior surface of the manubrium sterni. The clavicular head is broad and fleshy, with only a few tendinous fibres intermixed; it arises from the medial third of the upper surface of the clavicle. A narrow interval filled with fascia separates the heads below, but at a higher level the sternal portion overlaps the clavicular, and half-way up the neck the two heads unite into a fleshy mass which ascends to the mastoid portion of the temporal bone and occiput. There the muscle expands somewhat. At its insertion it is thick and tendinous where it is attached to the fore-part and lateral surface of the mastoid process; posteriorly it is thin and aponeurotic, and is inserted into rather more than half of the corresponding superior nuchal line of the occipital bone. In the dissection of the back, the latter part of the muscle was detached from the occiput.

The dissectors should note that the insertion of the sterno-mastoid into the skull is mainly posterior to the transverse axis of rotation of the atlanto-occipital joint. Therefore if one sterno-mastoid acts the head is drawn downwards to that side and the face is turned to the opposite side and tilted upwards. If both sterno-mastoids act simultaneously the head is drawn backwards. The muscle is supplied by the spinal part of the accessory nerve and by the second cervical nerve.

Dissection.—Turn the anterior border of the sterno-mastoid backwards and search for the arteries which supply it. At the level of the angle of the mandible the *sterno-mastoid branch of the occipital artery* will be found entering the deep surface of the muscle.

At the level of the cricoid cartilage the *sterno-mastoid branch of the superior thyreoid artery* enters the muscle, and a short

distance above the clavicle the muscle receives a branch from the *transverse scapular artery.*

When the arteries of supply have been noted, replace the anterior border of the muscle, remove the deep fascia in the region of the anterior triangle and expose the divisions and the contents of the triangle.

The Divisions of the Anterior Triangle.—After the deep fascia is removed, the dissector will recognise that each anterior triangle may be divided into three subsidiary areas

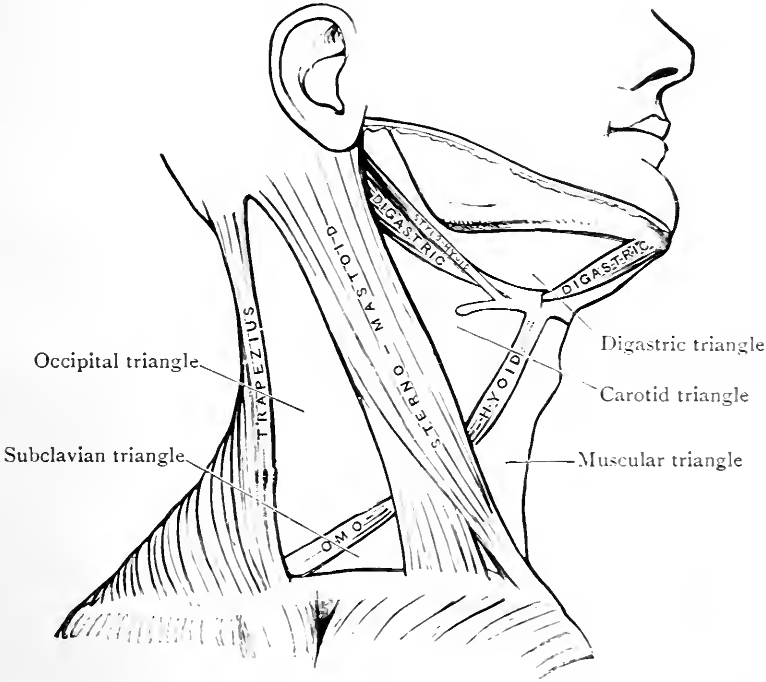

FIG. 43.—Diagram to show the boundaries of the Triangles of the Neck.

which are called the digastric, the carotid, and the muscular triangles, by means of the two bellies of the digastric muscle and the anterior belly of the omo-hyoid muscle.

The *digastric triangle* is bounded by the two bellies of the digastric muscle and the lower border of the mandible.

The boundaries of the *carotid triangle* are:—above and in front, the posterior belly of the digastric; below and in front, the anterior belly of the omo-hyoid; and, behind, the anterior border of the sterno-mastoid (Fig. 43).

The *muscular triangle* is bounded:—above and behind, by the anterior belly of the omo-hyoid; below and behind,

by the anterior border of the sterno-mastoid; and in front, by the middle line of the neck.

An additional triangle common to the two sides lies between the hyoid bone below, the two anterior bellies of the digastrics at the sides, and the mandible above. It is called *the submental triangle.*

Before commencing the dissection of the contents of the subsidiary parts of the anterior triangle the dissectors of both sides should, together, study the structures which lie in the middle line of the neck and immediately to either side of it; for the median area of the neck is of the highest importance to the surgeon. The area is divided by the hyoid bone into supra-hyoid and infra-hyoid portions.

Dissection.—Clean first the supra-hyoid area. Follow the upper ends of the anterior jugular veins through the very fatty superficial fascia, then remove the fat and expose the deep fascia which extends from the chin to the hyoid bone and connects together the anterior bellies of the digastric muscles of the opposite sides. Next remove that deep fascia; secure, if possible, the submental lymph glands (Fig. 44); and clean the mylo-hyoid muscles, and the median raphe between them which extends from the symphysis menti to the hyoid bone. When the supra-hyoid area has been displayed, turn to the infra-hyoid region, follow the anterior jugular veins downwards, and when they are cleaned pull them aside and, on each side, remove the deep fascia which descends from the hyoid bone to the sternum on the surfaces of the infra-hyoid muscles. As the fascia is removed two muscles at first come into view, one, nearer the median plane, descending from the hyoid bone to the sternum, it is the *sterno-hyoid.* On the same plane, but situated along the lateral border of the sterno-hyoid, the *anterior belly of the omo-hyoid* will be exposed. Near the sternum, and on a deeper plane, the anterior border of the lower part of the *sterno-thyreoid* will be exposed. After the muscles mentioned have been cleaned, take away the areolar tissue from between the medial borders of the muscles in the lower part of the neck and expose the third or *pretracheal layer of the deep cervical fascia* which covers the isthmus of the thyreoid body, and follow the fascia upwards to its attachment to the cricoid cartilage. At this stage look for a small muscle called the *levator glandulæ thyreoideæ* which may be present, extending upwards from the isthmus of the thyreoid body to the hyoid bone. Now note that so long as the pretracheal fascia is intact the isthmus of the thyreoid body cannot be displaced downwards, but when the pretracheal fascia has been cut through along the lower border of the cricoid cartilage the isthmus can be displaced downwards for a considerable distance, by means of the handle of the scalpel introduced through the incision in the fascia and used as a lever, and the upper rings of the trachea can thus be exposed. When the dissectors have demonstrated the above-mentioned facts they should clear away the pretracheal fascia from the isthmus

of the thyreoid body, secure the tributaries of the *inferior thyreoid veins* at its lower border, and follow them downwards to the upper aperture of the thorax; then clearing away the remains of the pretracheal fascia they should display the front of the lower part of the cervical portion of the trachea upon which the inferior thyreoid veins descend. At this stage a small artery, the *thyreoidea ima*, may occasionally be found ascending on the front of the trachea to the isthmus of the thyreoid body.

When the dissection of the lower part of the infra-hyoid area is completed return to the upper part. Clean the anterior ends of the crico-thyreoid muscles which spring from the cricoid cartilage; they run upwards and laterally, one on each side. Between the crico-thyreoid muscles, on a deeper plane, secure the *crico-thyreoid arteries*, which anastomose across the front of the median *crico-thyreoid ligament*. Note that the median crico-thyreoid ligament is attached below to the upper border of the cricoid cartilage, and above to the lower border of the thyreoid cartilage; then push the handle of the scalpel or a broad probe backwards along the surface of the *conus elasticus*, which is continuous with the median ligament, and note that it ascends medial to the thyreoid cartilage. It becomes continuous above (see Fig. 126), with the *vocal ligament*, but that fact cannot be demonstrated at the present stage of the dissection. Next clean the prominent anterior part of the thyreoid cartilage, which forms the laryngeal prominence in the front of the neck. Lastly, clean away the fascial tissue between the upper part of the thyreoid cartilage and the body of the hyoid bone and display the *middle thyreo-hyoid ligament* which extends from the upper border of the thyreoid cartilage behind the body of the hyoid bone to its upper border. As the fascia is removed from the upper part of the median thyreo-hyoid ligament behind the body of the hyoid bone a small bursal sac will be opened. It facilitates the movement of the hyoid bone over the upper part of the thyreoid cartilage during deglutition. When the dissection is completed revise the structures which have been exposed.

The Middle Line of the Neck.—In the *supra-hyoid part* of the median portion of the neck lie the structures which are concerned in the construction of the floor of the mouth. The dissector will have noticed already that the fatty superficial fascia was more fully developed there than elsewhere in the neck, and that the anterior margins of the two platysma muscles met and decussated in the median plane, for 10 or 12 mm. (about half an inch), below the chin. The anterior attachments of the bellies of the two digastric muscles to the mandible, one on each side of the symphysis, was noted. Thence they descend towards the hyoid bone, and diverge slightly from each other so as to leave between them a narrow triangular space, called the *submental triangle* (Fig. 44). The floor of the space is formed by the anterior portions of the

two mylo-hyoid muscles, whilst bisecting the floor of the triangle, in the median plane, is the fibrous raphe into which those muscles are inserted. Not infrequently the medial margins of the digastric muscles send decussating fibres across the interval. Within the submental triangle are the *submental*

FIG. 44.—Dissection of the Front of the Neck. The Right Sterno-mastoid has been removed.

glands, which receive lymph from the median part of the lower lip and chin and the anterior part of the tongue.

In the median area of the *infra-hyoid part* there is a narrow intermuscular interval, bounded on each side, above, by the medial margins of the sterno-hyoid muscles, and to a smaller extent, below, by the medial margins of the sterno-thyreoid muscles (Fig. 44); more laterally lie the anterior bellies

of the omo-hyoid muscles. In the median intermuscular interval the following structures will be found: (1) the median part of the thyreo-hyoid membrane; (2) the anterior border of the thyreoid cartilage, with the projecting prominentia laryngea (O.T. pomum Adami) at its upper end; (3) the arch of the cricoid cartilage; (4) the crico-thyreoid ligament, with the anastomosis between the crico-thyreoid arteries, and the anterior ends of the crico-thyreoid muscles; (5) the first ring of the trachea, with the anastomosis between the medial terminal branches of the superior thyreoid arteries; (6) the isthmus of the thyreoid gland; (7) the inferior thyreoid veins, and (8) the lower cervical rings of the trachea. Occasionally the third or middle lobe of the thyreoid gland and the levator glandulæ thyreoideæ, or one or other of them, is found extending upwards from the isthmus of the thyreoid gland. When it is present the middle lobe either terminates above in a pointed extremity or becomes continuous with a fibrous cord, the remains of the thyreo-glossal duct, which disappears in the region of the hyoid bone. The levator extends from the isthmus or from the third lobe, and is attached, above, to the lower border of the hyoid bone.

Dissection.—The superficial layers of the deep fascia must now be removed from the whole area of each anterior triangle, and for that purpose, and for the satisfactory dissection of the contents of the triangles, it is necessary that the head be turned well over to the opposite side; therefore the dissectors must arrange to work alternately.

Commence with the digastric triangle. Its boundaries are the lower border of the mandible and the two bellies of the digastric muscle.

Its contents are: (1) the lower part of the submaxillary gland; (2) the submaxillary lymph glands; (3) part of the external maxillary artery; (4) part of the anterior facial vein; (5) the mylo-hyoid nerve; (6) the mylo-hyoid artery; (7) a small part of the hypoglossal nerve; (8) a small part of the lingual vein.

Dissection.—Remove the deep fascia which was previously turned aside (p. 123) and clean the *submaxillary lymph glands*. Most of those glands lie immediately below the mandible, in the angle between it and the submaxillary gland, but some may be found on the superficial surface of the gland. Turn the gland upwards and fix it with hooks; then secure the *mylo-hyoid nerve and artery*, as they enter the posterior border of the anterior belly of the digastric about the middle of its length,

and the twig which the nerve gives to the mylo-hyoid muscle. Define the band of fascia which surrounds the intermediate tendon of the digastric and binds it to the greater cornu of the hyoid bone. Note that the tendon is embraced by the cleft lower end of the stylo-hyoid muscle. Clean the posterior belly of the digastric and the stylo-hyoid muscle, which descends along its anterior border. Note that the posterior belly of the digastric and the stylo-hyoid disappear, postero-superiorly, under cover of the angle of the mandible. Clean the anterior belly of the digastric, and then examine the floor or medial boundary of the triangle. Immediately behind the anterior belly of the digastric it is formed by the posterior fibres of the mylo-hyoid muscle; and more posteriorly and on a deeper plane it is formed by the hyoglossus muscle (Figs. 51, 68).

Clean the portion of the mylo-hyoid which is exposed and, at its posterior border, immediately above the greater cornu of the hyoid bone, secure the *hypoglossal nerve* and the lingual vein; the vein lies below the nerve. Displace the lingual vein and the hypoglossal nerve upwards; cut through the fibres of the hyoglossus, immediately above and parallel with the greater cornu, and display the lingual artery, which in that position lies immediately above the greater cornu, parallel with the lingual vein but separated from it by the hyoglossus muscle.

All the structures which have been mentioned above will be met with in the dissection of other regions, when a full account of them will be given.

Turn next to the carotid triangle, so called because it contains parts of the common, internal, and external carotid arteries. It is bounded posteriorly by the anterior border of the sterno-mastoid; above and anteriorly by the posterior belly of the digastric; and below and anteriorly by the anterior belly of the omo-hyoid.

Dissection.—Trace the anterior facial vein from the digastric triangle, across the superficial surface of the posterior belly of the digastric, to the posterior border of the muscle, where it unites with the posterior facial vein, which is descending from under cover of the lower end of the parotid gland. The trunk formed by the union of the anterior and posterior facial veins is the *common facial vein*. Trace the common facial vein downwards and backwards to its union with the *internal jugular vein*, at or under cover of the anterior border of the sterno-mastoid. Remove the deep fascia and the areolar tissue, and the lymph glands which lie in the angle between the posterior belly of the digastric and the anterior border of the sterno-mastoid, below the lower end of the parotid gland; secure the lingual vein, which passes backwards from the tip of the greater cornu of the hyoid bone to join the internal jugular vein; and the hypoglossal nerve, as it crosses, at a higher level, superficial to the internal and external carotid arteries. As the nerve turns forwards across the large arteries it is itself crossed, superficially, by the sterno-mastoid branch of

the occipital artery, and it gives off its *descending branch*. Trace the descending branch downwards, in the fascia which lies superficial to the lower part of the internal and the upper part of the common carotid arteries, to the point where it disappears under cover of the anterior belly of the omo-hyoid, avoiding injury to the lingual, common facial, and superior thyreoid veins;[1] and secure the *communicating branches*, from the second and third cervical nerves, which join its posterior aspect. The latter nerves may cross either superficial or deep to the internal jugular vein. Return to the hypoglossal nerve at the point where it gives off its descending branch, and trace it forwards to the upper aspect of the posterior end of the greater cornu of the hyoid bone, where it gives off the branch of supply to the thyreo-hyoid muscle. Trace the branch into that muscle, below the level of the greater cornu; then follow the trunk of the hypoglossal anteriorly to the digastric triangle. Note that as it runs forwards it passes deep to the posterior belly of the digastric and the stylo-hyoid muscle, and superficial to the hyoglossus, which ascends to the tongue from the upper border of the greater cornu. Remove the fascial sheath from the superficial surfaces of the lower parts of the *internal and external carotid arteries*, and from the upper part of the *common carotid artery*. Note that the latter divides into the two former at the level of the upper border of the thyreoid cartilage, and that the external carotid is at first medial and anterior to the internal carotid.

Five branches may spring from the external carotid artery in the carotid triangle—three from its anterior surface: the *superior thyreoid*, the *lingual* and the *external maxillary*; one from its medial surface, the *ascending pharyngeal*; and one from its posterior surface, the *occipital*; but not uncommonly the occipital and the external maxillary arise, beyond the limits of the carotid triangle, under cover of the posterior belly of the digastric. The superior thyreoid springs from the front of the lower part of the external carotid, below the level of the greater cornu of the hyoid, and runs downwards towards the lower angle of the carotid triangle, where it disappears under cover of the anterior belly of the omo-hyoid. The lingual arises about the level of the tip of the greater cornu. It runs forwards above the level of the cornu, forming a loop, convex upwards, which lies deep to the hypoglossal nerve; and it disappears under cover of the posterior border of the hyoglossus muscle. The ascending pharyngeal branch, which springs from the medial surface of the lower end of the external carotid, ascends on a deeper plane, between the external and internal carotids and the wall of the pharynx, and will be followed at a later stage of the dissection. The external maxillary and the occipital arise immediately below the posterior belly of the digastric and almost at once disappear under cover of the muscle; not uncommonly they arise under cover of its lower border. Before proceeding to

[1] The lingual vein may join the common facial vein, in which case the latter usually enters the internal jugular opposite the interval between the hyoid bone and the thyreoid cartilage, as in the specimen depicted in Fig. 12. The superior thyreoid vein either ends in the internal jugular or joins the common facial vein opposite the thyreo-hyoid interval.

clean the branches of the external carotid, secure the *internal and external laryngeal branches of the superior laryngeal branch of the vagus nerve.* The *internal* branch will be found in the posterfor part of the thyreo-hyoid interval below the greater cornu of the hyoid bone and behind the posterior border of the thyreo-hyoid muscle, beneath which it disappears. It is accom-

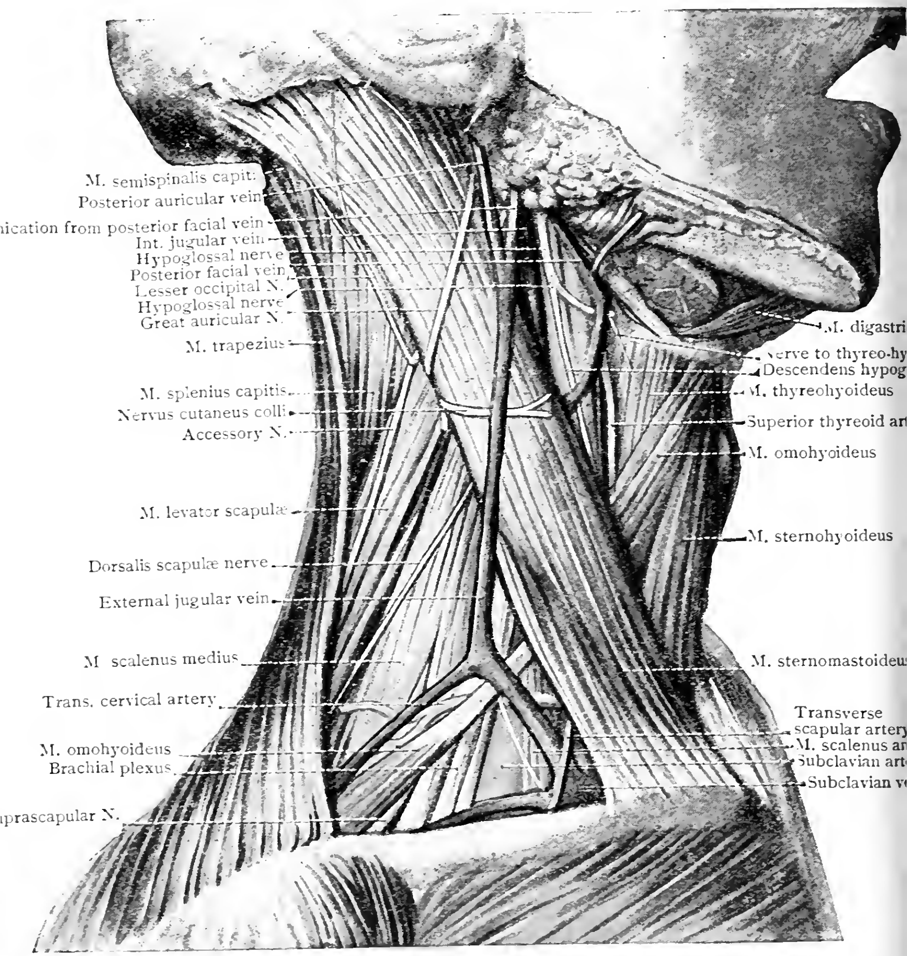

FIG 45.—The Triangles of the Neck seen from the side. The clavicular head of the sterno-mastoid muscle was small, and therefore a considerable part of the scalenus anterior muscle is seen.

panied by the *laryngeal branch of the superior thyreoid artery.* The external branch is more difficult to find ; but if the superior thyreoid artery and the upper part of the common carotid are displaced posteriorly, the nerve will be found, lying deep to them, in the fascia which covers the anterior part of the inferior constrictor muscle.

Remove the fascia from the surface of the internal jugular vein, which overlaps the anterior borders of the common

and internal carotid arteries. Dissect in the interval between the vein and the arteries and secure the *vagus nerve*, which lies deeply.

Remove the remains of the fascia from the carotid arteries and the internal jugular vein, but avoid injury to the hypoglossal nerve and its branches; and note the presence of the *upper deep cervical lymph glands* which lie on the superficial surfaces of the great arteries and the internal jugular vein. The glands are sometimes very large, and the dissectors should remember that they receive lymph from the face, the mouth and tongue, the posterior part of the nose and the upper part of the pharynx. After the large vessels are cleaned, remove the fascia from the branches of the external carotid artery and the twigs they give off, so far as they lie in the region of the carotid triangle. Commence with the superior thyreoid. Immediately after its origin it gives off a small infra-hyoid branch, then a laryngeal branch which accompanies the internal laryngeal branch of the superior laryngeal nerve; and, just before it disappears under cover of the anterior belly of the omo-hyoid, a sterno-mastoid branch arises from its posterior border and runs downwards and backwards, along the upper border of the omo-hyoid, across the superficial aspect of the common carotid artery and the internal jugular vein. Next, clean the lingual artery and note its small supra-hyoid branch. The external maxillary artery gives off no branches in the carotid triangle, but a sterno-mastoid branch of the occipital artery will usually be found passing downwards and backwards, superficial to the loop of the hypoglossal nerve. Push the lower border of the parotid gland upwards, and immediately under cover of it, at the level of the angle of the mandible, secure the *accessory nerve*, as it emerges from under cover of the posterior belly of the digastric and crosses superficial to the internal jugular vein. It is sometimes accompanied by an additional branch to the sterno-mastoid from the occipital artery.

The floor or medial boundary of the carotid triangle is formed by the upper part of the thyreo-hyoid muscle, the posterior part of the hyoglossus and the middle and inferior constrictors of the pharynx. The latter two muscles cannot be displayed at present, but the thyreo-hyoid is exposed below the greater cornu of the hyoid bone, and part of the hyoglossus can be seen in the angle between the greater cornu of the hyoid and the lower part of the posterior belly of the digastric.

The Muscular Triangle.—When the deep fascia which covers the muscular triangle is removed, portions of three muscles are brought into view. Postero-superiorly is the anterior belly of the omo-hyoid; more anteriorly and on the same plane is the sterno-hyoid; and below and anterior to the sterno-hyoid, but on a deeper plane, is a small part of the sterno-thyreoid.

The muscles mentioned may be considered to form the

floor or medial boundary of the triangle, and, if this view is taken, the structures they cover, which lie more deeply, are under cover of the floor. Those structures must now be exposed.

Dissection.—Divide the anterior belly of the omo-hyoid along the anterior border of the sterno-mastoid and turn it upwards to its insertion into the hyoid bone. As that is done its twig of supply from the loop called the ansa hypoglossi will be cut. The *ansa hypoglossi* is formed by the union of the descending branch of the hypoglossal nerve and the communicating branch from the cervical plexus. Divide the sterno-hyoid as low down as possible ; turn it upwards to its insertion into the body of the hyoid bone and note its nerve of supply from the ansa hypoglossi. Secure the nerve to the sterno-thyreoid from the ansa hypoglossi ; then remove the fascia and expose the lower part of the thyreo-hyoid muscle, the greater part of the sterno-thyreoid and the anterior part of the thyreoid cartilage. Note that the sterno-thyreoid is inserted into an oblique line on the outer surface of the lamina of the thyreoid cartilage and that the thyreo-hyoid springs from the same line and is inserted into the greater cornu of the hyoid bone. The crico-thyreoid branch of the superior thyreoid artery may be found passing downwards and forwards along the upper end of the sterno-thyreoid, accompanied by the external laryngeal nerve ; or the nerve and the vessel may lie deep to the upper end of the muscle.

Divide the sterno-thyreoid as low down as possible and turn it upwards to its insertion ; remove the fascia under cover of it and expose the lobe of the thyreoid gland, enclosed in its fascial sheath. Below it, a small part of the side of the trachea will be seen.

The dissector should note that whilst the sterno-mastoid remains undisturbed the posterior part of the lobe of the thyreoid gland and its lower extremity are not exposed, but if the sterno-mastoid is displaced backwards the whole of the lateral surface of the lobe is brought into view. The dissector should note also that, until the sterno-mastoid is displaced backwards, only a small portion of the upper end of the common carotid and the lower parts of the internal and external carotid arteries are visible ; indeed, the common carotid may be entirely concealed. Only a small part of the anterior border of the internal jugular vein projects anterior to the sterno-mastoid in the upper angle of the carotid triangle ; and it also is not uncommonly hidden when the sterno-mastoid is well developed. During life, however, when the muscle is soft and pliable the structures concealed by it are readily exposed, for the muscle is easily displaced backwards after the fascia has been divided along its anterior border.

In dissecting-room subjects, in which the muscles have been hardened by formol, it is not possible to obtain a proper view of the course and relations of the common carotid artery and the internal jugular vein, or to appreciate the relations of the first part of the subclavian artery and the relations of the scalenus anterior muscle, until the sterno-mastoid has been reflected. Divide the external jugular vein immediately below its origin by

the union of the posterior auricular vein with the communication from the posterior facial vein, and turn it downwards. Divide the great auricular nerve at the level of the angle of the mandible and turn it backwards; and turn backwards also the nervus cutaneus colli, whose two terminal branches have been cut already. The clavicular head of the sterno-mastoid was cut when the clavicle was removed; now divide the sternal head, turn the muscle upwards towards its insertion. As the muscle is turned upwards, sterno-mastoid branches of the transverse scapular, superior thyreoid, and occipital arteries will be exposed; and if they interfere with the reflection of the muscle they must be divided. Slightly above the level of the sterno-mastoid branch of the occipital artery the accessory nerve will be found passing through the deeper fibres of the muscle, and care must be taken to avoid injury to it; but it may be dissected out of the muscle and left in position on the lateral surface of the internal jugular vein.

Deep Cervical Fascia.—When the sterno-mastoid has been reflected, a deep fascial plane of the neck is exposed in which lie many lymph glands. Before carrying the dissection further the dissector should reconsider the arrangement of the deep cervical fascia. He has already seen that it forms a complete sheath enclosing the muscles of the neck and the structures which lie between and under cover of them. The general arrangement of the fascia is studied best on transverse sections of the neck made at the level of the isthmus of the thyreoid gland and a short distance above the sternum. At the former level it is possible to recognise (1) a superficial layer; (2) a pretracheal layer; (3) a prevertebral layer; and (4) a fascial sheath which encloses the common carotid arteries, the internal jugular vein and the vagus nerve, as they lie in the angular interval between the sterno-mastoid laterally, the thyreoid gland, the trachea, œsophagus medially, and the prevertebral muscles posteriorly.

The *first or superficial layer*, as it is traced backwards, splits to enclose the sterno-mastoid muscle (Fig. 47). Beyond the sterno-mastoid it passes backwards to the anterior border of the trapezius muscle, forming the roof of the posterior triangle; then it splits again to enclose the trapezius, along the surfaces of which it is prolonged till it blends with the supraspinous ligaments and the ligamentum nuchæ. The lamella which covers the deep surface of the sterno-mastoid is blended with the lateral surface of the carotid sheath. The *pretracheal layer*, which has been dissected already in the median plane, ensheaths the thyreoid gland and blends

postero-laterally with the medial surface of the carotid sheath. The *prevertebral layer* covers the anterior surfaces of the prevertebral muscles, and, passing laterally, blends with the posterior aspect of the carotid sheath; then, turning round the tips of the transverse processes of the vertebræ, it passes backwards, covering the muscles which form the floor of the posterior triangle; and it becomes continuous with the sheaths of the deep muscles of the back of the neck.

Laterally and posteriorly, the superficial layer of the deep fascia passes upwards over the sterno-mastoid and the trapezius to be attached to the superior nuchal lines and the mastoid portions of the temporal bones. In the anterior cervical region it is attached to the body and the greater cornua of the hyoid bone, and then, as it is prolonged further upwards, it splits anteriorly to enclose the submaxillary gland, and posteriorly to enclose the parotid. It has been noted already that the lamella which passes superficial to the submaxillary gland is attached to the lower border of the mandible, and that which passes deep to the gland is connected above to the mylo-hyoid line on the inner surface of the mandible. The layer which passes superficial to the parotid gains attachment to the zygoma and is prolonged forwards to blend with the fascia covering the masseter. The lamella which passes deep to the parotid covers its postero-medial and antero-medial surfaces; the posterior part is attached above to the lower border of the tympanic plate, and the anterior part to the posterior border of the petro-tympanic fissure (O.T. Glaserian). It also gains an inter-

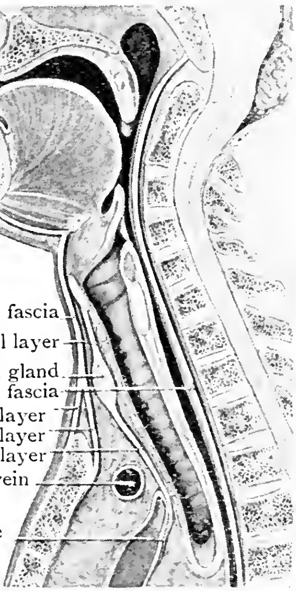

FIG. 46.—Diagram of deep Cervical Fascia in sagittal section.

mediate attachment to the styloid process and to the posterior border of the angle of the mandible. That portion is relatively thick; it lies in relation with the lower part of the antero-medial surface of the parotid and is known as the *stylo-mandibular ligament.*

When the superficial layer is traced downwards it is found to split, between the cricoid cartilage and the sternum, into two lamellæ. The more superficial of the two lies superficial to the sterno-mastoid and is attached, below, to the upper border of the sternum and the upper border of the clavicle. In the anterior region the deeper lamella descends upon the anterior surfaces of the infra-hyoid muscles and is attached, below, to the posterior surface of the manubrium; laterally, it passes deep to the sterno-mastoid and is fused with the lateral border of the carotid sheath. In the posterior triangle the deeper lamella ensheaths the posterior belly of the omo-hyoid and binds it down to the posterior border of the clavicle and the cartilage of the first rib. The space between the two lamellæ has been called the supra-sternal space. Its boundaries and contents have been fully described already (p. 122).

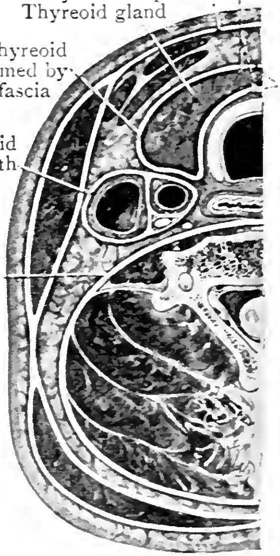

FIG. 47.—Diagram of deep Cervical Fascia in transverse section at the level of the thyreoid gland.

The upper attachment of the *pretracheal layer* is to the cricoid cartilage and to the laminæ of the thyreoid cartilage, below the insertion of the sterno-thyreoid muscle. At its lower end it blends with the fibrous pericardium in the middle mediastinum.

The *prevertebral layer* can be followed upwards to the base of the skull, where it is attached, in the anterior cervical region, to the posterior and medial margins of the jugular foramen and to the basilar part of the occipital bone, anterior to the insertions of the prevertebral muscles and posterior to the superior constrictor of the pharynx. Below, it blends

with the fascia on the anterior aspect of the vertebral column in the posterior mediastinal region.

The Carotid Sheath.—The term carotid sheath is applied to the fascia which surrounds and embeds the carotid arteries, the internal jugular vein, and the vagus nerve. Part of it has been removed already, and the dissector will have noted that it is in no sense a membrane, but merely the fibro-areolar tissue which fills the interval between the transverse processes of the vertebræ posteriorly, the trachea, larynx, pharynx, œsophagus, and the lobe of the thyreoid gland medially, and the sterno-mastoid laterally; that it is continuous with the fascial planes in its immediate neighbourhood, and that

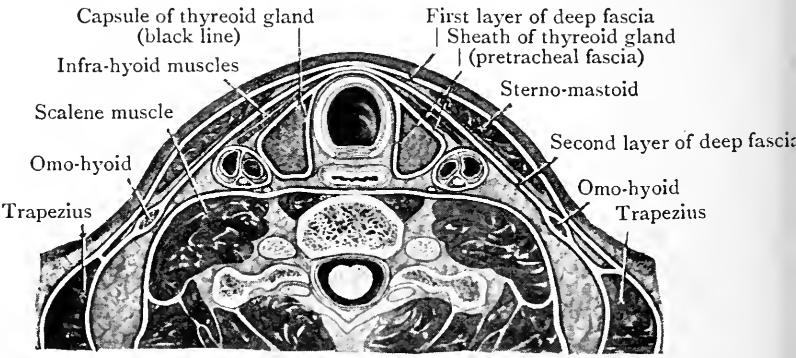

FIG. 48.—Diagram of the deep Cervical Fascia in a transverse section of the lower part of the neck.

through it run the carotid arteries, the internal jugular vein, and the vagus nerve, each in its own special compartment.

> ***Dissection.***—Remove the areolar tissue and the glands which lie under cover of the sterno-mastoid; stitch together the two parts of the divided anterior belly of the omo-hyoid muscle and fix the muscle to the common carotid artery and the internal jugular vein with one or two stitches; then proceed to display the structures which lie under cover of the sterno-mastoid. A glance at the following list will convince the dissector that they are very numerous.

Structures under cover of the Sterno-Mastoid.

Muscles.—The upper part of the splenius capitis; the upper and posterior part of the posterior belly of the digastric; the origins of the levator scapulæ, the scalenus medius, the longus capitis (O.T. rectus capitis anticus major), the rectus

39. Splenius capitis muscle.
40. Sterno-mastoid muscle.

capitis lateralis and the scalenus anterior; the intermediate tendon of the omo-hyoid, and the lower and posterior part of the sterno-hyoid and sterno-thyreoid.

Arteries.—The upper part of the common carotid (the lower part is still concealed by the lower part of the omo-hyoid and the lower parts of the sterno-hyoid and sterno-thyreoid muscles); the transverse scapular and its sterno-mastoid branch; the transverse cervical; the sterno-mastoid branch of the superior thyreoid; the occipital and its sterno-mastoid branches.

Veins.—The greater part of the internal jugular vein; the lower transverse portion of the anterior jugular vein; and, occasionally, the lower end of the external jugular vein, when that vessel dips forwards to its termination.

Nerves.—The cervical plexus and its branches, including the phrenic nerve; part of the accessory nerve.

If the lower parts of the divided sterno-hyoid and sterno-thyreoid muscles are displaced downwards, the lower part of the common carotid and the commencement of the first part of the subclavian artery will be exposed. Crossing the front of the latter are the lower portion of the cervical part of the vagus and a strand of sympathetic fibres called the ansa subclavia; on the left side, the subclavian artery and the ansa are concealed by the commencement of the innominate vein. At the same time the middle thyreoid vein will be exposed, and the posterior border of the lobe of the thyreoid gland also.

Dissection.—Commence by cleaning the anterior rami of the cervical nerves, from the second to the eighth, as they emerge between the muscles attached to the tubercles of the transverse processes of the cervical vertebræ. The first nerve, which turns downwards anterior to the transverse process of the atlas, will be exposed later. As the upper nerves are cleaned the dissectors will find that the second is connected to the third, and the third to the fourth, by looped strands, convex posteriorly, which constitute the lower two loops of the cervical plexus. The second nerve is connected with the first also by a loop, convex anteriorly, which passes upwards anterior to the transverse process of the atlas and posterior to the upper part of the internal jugular vein. It can be exposed if the vein is pulled forwards; and the dissector must at the same time secure the twigs of connection which pass from the medial side of the loop to the hypoglossal nerve and to the superior cervical ganglion of the sympathetic trunk, which lies behind the upper part of the internal carotid artery.

After the dissector has defined the loops of the plexus he

should trace the remains of the lesser occipital, the great auricular, the nervus cutaneus colli and the supraclavicular branches, which he displayed in the posterior triangle, to their origins from the roots of the plexus. The communicating branches which pass forwards to the descendens hypoglossi from the second, and sometimes also from the third cervical nerve, must be followed; they may cross either superficial or deep to the internal jugular vein. Then the phrenic nerve, which springs

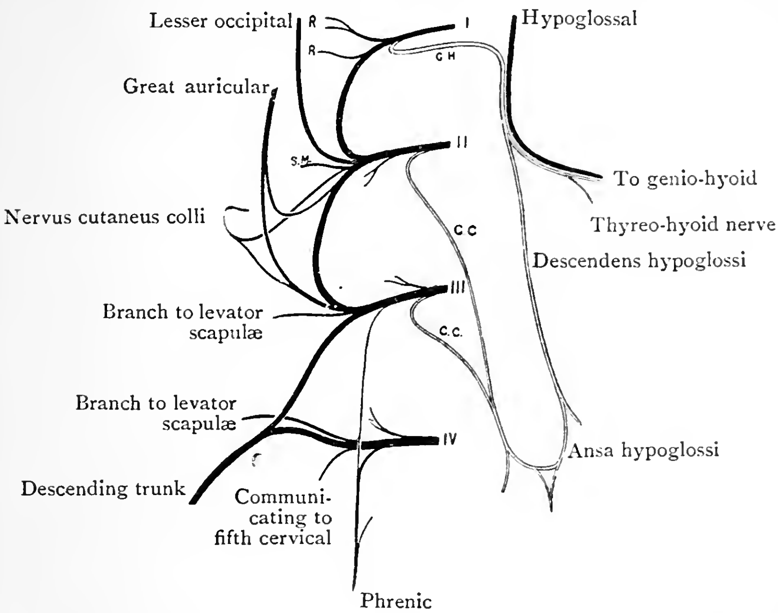

FIG. 50.—Diagram of the Cervical Plexus and the Ansa Hypoglossi.

I, II, III, IV.—Anterior rami of the upper four cervical nerves.

R. Branches to recti and longus capitis.
S.M. Branches to the sterno-mastoid.
C.C. Rami communicantes cervicales.
C.H. Communicating branch to hypoglossal.

This diagram shows that the descendens hypoglossi, the branch to the thyreo-hyoid, and in all probability the branches to the genio-hyoid, are composed of fibres given to the hypoglossal by the communicating twigs it receives from the first cervical nerve.

from the fourth cervical nerve, and receives additional twigs from the third and fifth nerves, must be followed downwards and medially, till it disappears under cover of the lower part of the internal jugular vein. It lies upon the surface of the scalenus anterior and passes deep to the omo-hyoid muscle and the transverse cervical and transverse scapular arteries. Running upwards parallel with, and anterior to it, is the ascending cervical branch of the inferior thyreoid artery.

Plexus Cervicalis.—The cervical plexus is a looped plexus formed by the first four cervical nerves. It lies in the upper

part of the side of the neck, under cover of the sterno-mastoid. The upper loop of the plexus, which connects the first and second nerves together, is directed forwards and lies between the internal jugular vein anteriorly, and the transverse process of the atlas posteriorly. The second and third loops, which unite the second and third and the third and fourth nerves, are directed backwards; and they lie on the superficial surface of the upper part of the scalenus medius muscle. The first loop is connected with the upper ganglion of the sympathetic trunk and with the hypoglossal nerve; and the roots of the second, third, and fourth nerves also are connected, by grey rami, with the upper cervical sympathetic ganglion.

The branches of the plexus are divisible into two main groups, the superficial and the deep. *The deep branches* are separable into two groups: the anterior, which run forwards, and the posterior, which run backwards; and the *superficial branches* are classified as ascending, transverse, and descending.

The *anterior group of deep branches* includes: (1) The ramus communicans cervicalis (p. 131), and (2) the phrenic nerve. (3) Less important muscular branches, from the first loop to (*a*) the rectus capitis lateralis; (*b*) the rectus capitis anterior (O.T. rectus capitis anticus minor); (*c*) the longus capitis (O.T. rectus capitis anticus major). (4) Muscular branches, from the third and fourth nerves, to the longus colli.

The *posterior group of deep branches* is formed by: (1) The communicating branches to the accessory nerve. (2) Branches of supply to: (*a*) the sterno-mastoid, from the second nerve; (*b*) the levator scapulæ, from the third and fourth; (*c*) the trapezius, from the third and fourth; (*d*) the scalenus medius, from the second, third, and fourth.

The *ascending group of superficial branches* is formed by the lesser occipital and great auricular nerves. The *transverse branch* is the nervus cutaneus colli; and the *descending branches* are the supraclavicular nerves. All the superficial nerves have already been traced in the earlier stages of the dissection (pp. 34, 35). The small muscular branches require no special notice, but the phrenic nerve requires careful consideration.

Nervus Phrenicus.—The importance of the phrenic nerve depends upon the fact that it is the nerve of supply to the chief muscle of respiration, the diaphragm. The majority of its fibres spring from the fourth cervical nerve, but it receives

49. Superficial temporal vessels and auriculo-temporal nerve.

twigs from the third and, not uncommonly, from the fifth nerve also. It descends from the neck through the superior and middle mediastinal regions of the thorax, and, after piercing the diaphragm, it is distributed on its lower surface. Only the cervical portion of the nerve belongs to the dissector of the neck; the remainder is displayed by the dissector of the thorax (p. 43, Vol. II.). In the neck, the nerve runs downwards and medially, on the superficial surface of the scalenus anterior, which forms its deep relation. It is covered by skin, superficial fascia and platysma, deep fascia and the sterno-mastoid; deep to the sterno-mastoid, it is overlapped by the internal jugular vein, and it is crossed by the omo-hyoid, the anterior jugular vein, and the transverse cervical and transverse scapular arteries; in addition, the left nerve is crossed by the thoracic duct, and the right nerve by the right lymph duct. At the root of the neck it passes from the medial border of the anterior scalene to the anterior surface of the first part of the subclavian artery; on the right side it crosses the artery, on the left it descends in front of it; it is covered anteriorly, on both sides, by the clavicle and by the commencement of the innominate vein; and it crosses either anterior or posterior to the internal mammary artery. It gives off no branches in the neck, but it sometimes receives a communication from the nerve to the subclavius.

After the dissector has completed the examination of the formation, the relations, and the branches of the cervical plexus, he should replace the divided infra-hyoid muscles in position and study their attachments and relations.

The **Infra-hyoid Muscles** are a series of flat, band-like muscles which lie upon the trachea, thyreoid gland, and larynx. They are disposed in two strata—viz., the omo-hyoid and the sterno-hyoid constituting a superficial layer; and the sterno-thyreoid and thyreo-hyoid a deep layer.

Musculus Omohyoideus.—The omo-hyoid is a two-bellied muscle. The *posterior belly* springs from the upper border of the scapula and the upper transverse scapular ligament. It crosses the posterior triangle of the neck, dividing it into occipital and subclavian portions, and terminates, under cover of the sterno-mastoid muscle, in an intermediate tendon. The muscle is superficial to the brachial plexus, and the tendon is superficial to the phrenic nerve and the scalenus anterior. The tendon is held in position by a strong process

of cervical fascia which is firmly attached below to the sternum and the first costal cartilage. The *anterior belly* emerges from under cover of the anterior border of the sterno-mastoid, and takes an almost vertical course through the anterior triangle. It is inserted into the lower border of the body of the hyoid bone, at the lateral side of the sterno-

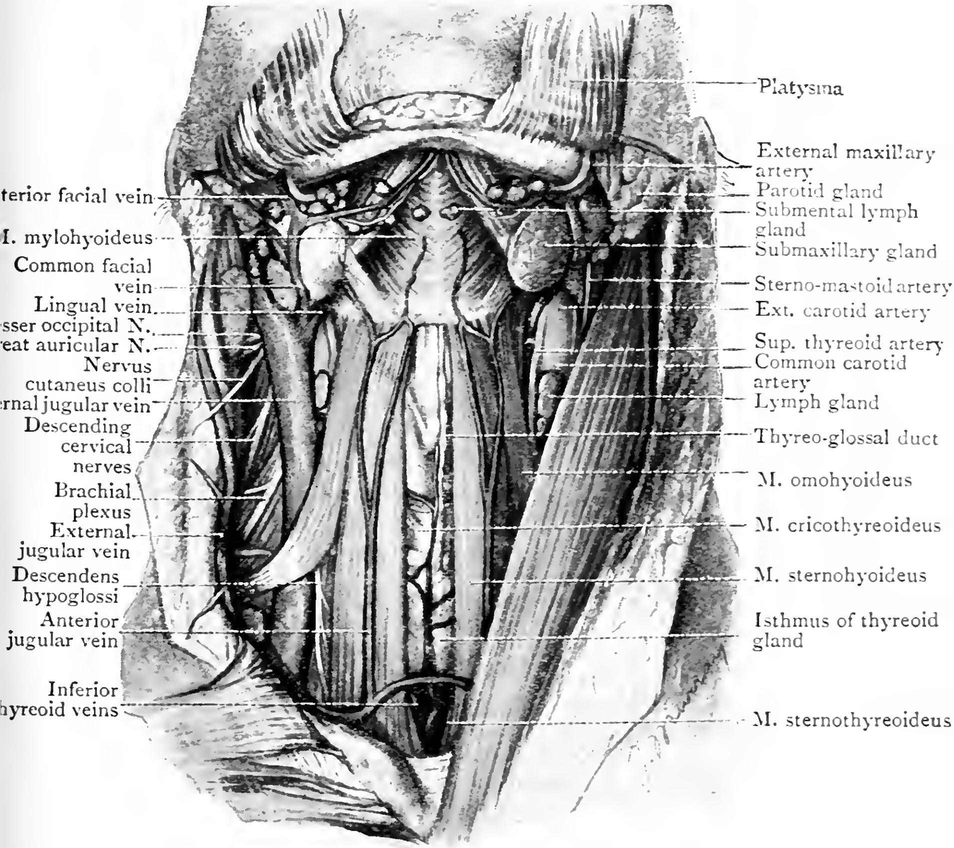

FIG. 52.—Dissection of the Front of the Neck. The right sterno-mastoid has been removed.

hyoid. In the anterior triangle of the neck it forms the boundary between the carotid and the muscular subdivisions, and it lies superficial to the internal jugular vein, the common carotid artery, the descendens hypoglossi, the superior thyreoid artery, the external laryngeal nerve, the attachments of the sterno-thyreoid and thyreo-hyoid muscles to the lamina of the thyroid cartilage; and immediately

below its insertion it covers part of the thyreo-hyoid membrane. Both bellies are supplied by branches from the *ansa hypoglossi*. Acting from the scapula it pulls the hyoid bone downwards and slightly backwards.

Musculus Sternohyoideus.—The sterno-hyoid muscle arises from the posterior aspect of the medial end of the clavicle, the posterior sterno-clavicular ligament, and the posterior surface of the manubrium sterni. It is inserted into the lower border of the body of the hyoid bone, between the median plane and the insertion of the omo-hyoid. A short distance above the sternum an oblique tendinous intersection frequently divides it into two portions. The lower part of the muscle is covered by the sterno-mastoid, and it is crossed by the anterior jugular vein. Its principal deep relations are the lower part of the common carotid artery and the sterno-thyreoid muscle, which separates it from the lateral lobe of the thyreoid gland. It is supplied by branches from the *ansa hypoglossi*. It pulls the hyoid bone downwards.

Musculus Sternothyreoideus.—The sterno-thyreoid muscle lies under cover of the preceding and is broader but shorter. It springs from the posterior aspect of the manubrium sterni and from the cartilage of the first rib. Diverging slightly from its fellow as it ascends, it is inserted into the oblique line on the lateral face of the lamina of the thyreoid cartilage, parallel with and immediately below the thyreo-hyoid. An incomplete tendinous intersection may sometimes be noticed interrupting its muscular fibres. In the neck, it is covered in the greater part of its extent by the sterno-hyoid; but the posterior part of its insertion is covered by the anterior belly of the omo-hyoid; and the lower and anterior part is covered by skin and fascia only. The nerve supply is derived from the *ansa hypoglossi*. It pulls the thyreoid cartilage downwards.

Musculus Thyreohyoideus.—The thyreo-hyoid muscle lies on the same plane as the sterno-thyreoid, and may be regarded as its upward continuation. It takes origin from the oblique line on the lateral surface of the lamina of the thyreoid cartilage, and is inserted into the lower border of the greater cornu of the hyoid bone, under cover of the omo-hyoid muscle. It conceals part of the lamina of the thyreoid cartilage and the lateral part of the thyreo-hyoid membrane, and the aperture in the membrane through which the laryngeal branch of the superior thyreoid artery and the

internal laryngeal nerve enter the pharynx. It is supplied by a twig from the *hypoglossal nerve.* It approximates the hyoid bone to the thyreoid cartilage.

Dissection.—The dissectors of the head and neck should now proceed to study the relations of the common carotid and subclavian arteries, the cervical part of the thoracic duct, and the dome of the pleura, before those structures are disturbed by the dissectors of the thorax. Whilst this is being done, the omohyoid must be retained in position, but the upper and lower portions of the other infra-hyoid muscles may be turned upwards and downwards respectively.

Remove the remains of the fascial sheath from around the common carotid artery and the adjacent part of the internal jugular vein. Separate the vein from the artery, and clean the portion of the vagus nerve which lies between them on a posterior plane. Note that, on the right side, the nerve crosses the anterior surface of the subclavian artery, and there gives off its recurrent branch ; and that, on the left side, it lies medial to the subclavian artery, and in an anterior plane.

After the lower parts of the cervical portions of the vagi have been cleaned, look for the terminal part of the thoracic duct, on the left side, and for the right lymph duct, on the right side. In seeking for the thoracic duct, pull the lower end of the left internal jugular vein aside and displace the common carotid artery forwards ; then look for the duct, as it turns laterally from the border of the œsophagus, a little below the level of the cricoid cartilage ; trace it, posterior to the internal jugular vein, to its termination in the commencement of the innominate vein. On the right side, look for the right lymph duct entering the innominate vein in the angle of union of the internal jugular and subclavian veins. Next, look for the cervical portion of the sympathetic trunk, which descends posterior to the common carotid. Clean the nerve trunk carefully and clean also the inferior thyreoid artery, which crosses anterior or posterior to it, at the level of the cricoid cartilage. Displace the common carotid laterally, and in the angle between the borders of the trachea and the œsophagus find the recurrent branch of the vagus ; trace it upwards to the point where it disappears under cover of the lobe of the thyreoid gland, and downwards to the subclavian artery.

Arteria Carotis Communis.—The common carotid artery arises differently on the two sides. On the right side, it arises as a terminal branch of the innominate artery, behind the sterno-clavicular joint; on the left side, it springs from the aortic arch, in the superior mediastinum. The left artery ascends to the back of the left sterno-clavicular articulation. From the sterno-clavicular joint each common carotid artery runs upwards, backwards, and slightly laterally to the level of the upper border of the thyreoid cartilage, which lies opposite the fibro-cartilage between the third and fourth cervical

vertebræ; there it ends by dividing into its two terminal branches—the internal and the external carotid arteries.

Superficial Relations.—Above the level of the anterior belly of the omo-hyoid the common carotid artery is covered by the skin, the superficial fascia and the platysma, the deep fascia and the anterior margin of the sterno-mastoid. It is crossed, immediately above the omo-hyoid, by the sterno-mastoid branch of the superior thyreoid artery, and, at a higher level, by the superior thyreoid vein; and it is overlapped by the anterior margin of the internal jugular vein. In the lower part of its extent it lies more deeply: its superficial relations are,—the skin and superficial fascia, the deep fascia

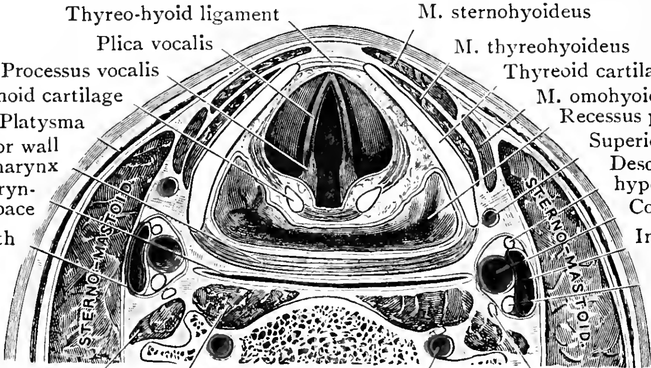

FIG. 53.—Transverse section through the Neck at the level of upper part of Thyreoid Cartilage.

and the sterno-mastoid; the anterior jugular vein, crossing transversely, deep to the sterno-mastoid and above the upper border of the clavicle; the omo-hyoid, the sterno-hyoid, and the sterno-thyreoid muscles. Deep to the muscles, the branches of the *ansa hypoglossi* descend in front of its sheath; and the middle thyreoid vein crosses it to join the internal jugular vein (Fig. 51).

Posterior to it lie the transverse processes of the cervical vertebræ and the origins of the longus colli, longus capitis and the scalenus anterior. The sympathetic trunk is directly behind it, and the vagus is postero-lateral to it. The inferior thyreoid artery crosses posterior to it, at the level of the cricoid cartilage; and the vertebral artery lies between it and the transverse process of the seventh cervical vertebra. On the

right side, the recurrent nerve crosses posterior to it, immediately above its origin; and on the left side, the thoracic duct turns laterally behind it, between it and the vertebral artery.

To its medial side, below, lie the trachea and œsophagus, with the recurrent nerve in the angle between their adjacent borders; and to the medial side of its upper part are the larynx and pharynx. The lobe of the thyreoid gland lies either medial to the artery, separating it from the œsophagus, pharynx, trachea, and larynx, or it forms a direct anterior relation (Figs. 48, 53). Between its upper extremity and the inferior constrictor muscle of the pharynx lies the glomus caroticum.

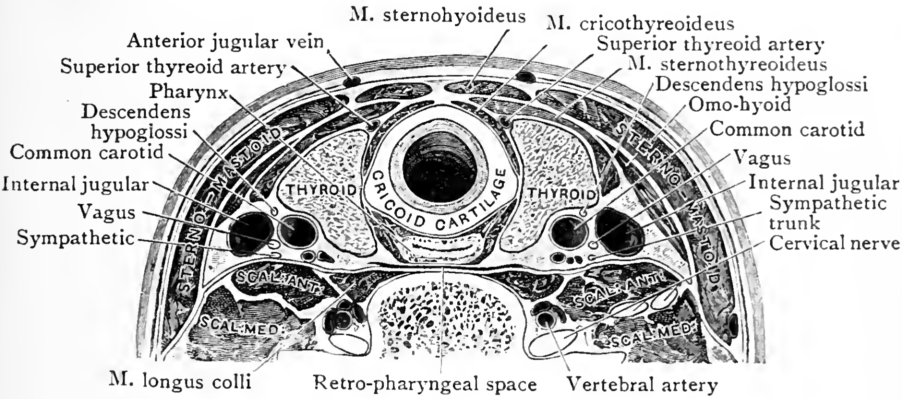

FIG. 54.—Transverse section through the Neck at the level of the Cricoid Cartilage.

As a rule, the terminal divisions are the only branches of the common carotid, but occasionally the superior thyreoid or the ascending pharyngeal artery arises from it, instead of from the external carotid. That is more especially the case when the division of the common carotid takes place at a higher level than usual.

Glomus Caroticum.—The glomus caroticum is a little, oval, reddish-brown body, placed upon the deep aspect of the common carotid artery at the point where it bifurcates. To expose it, therefore, the vessel must be twisted round in such a manner that its posterior surface is turned forwards. It is closely connected with the sympathetic filaments which twine around the carotid vessels; and in structure it is similar in its nature to the glomus coccygeum, which rests upon the anterior aspect of the coccyx. It is included, therefore, in the group of ductless glands. Entering it are numerous minute arterial twigs, which take origin from the termination of the common carotid and the commencement of the external carotid. The

function of the remarkable little body is quite unknown, but it belongs to the system of chromophil organs.

Arteria Subclavia.—The relations of the third part of the

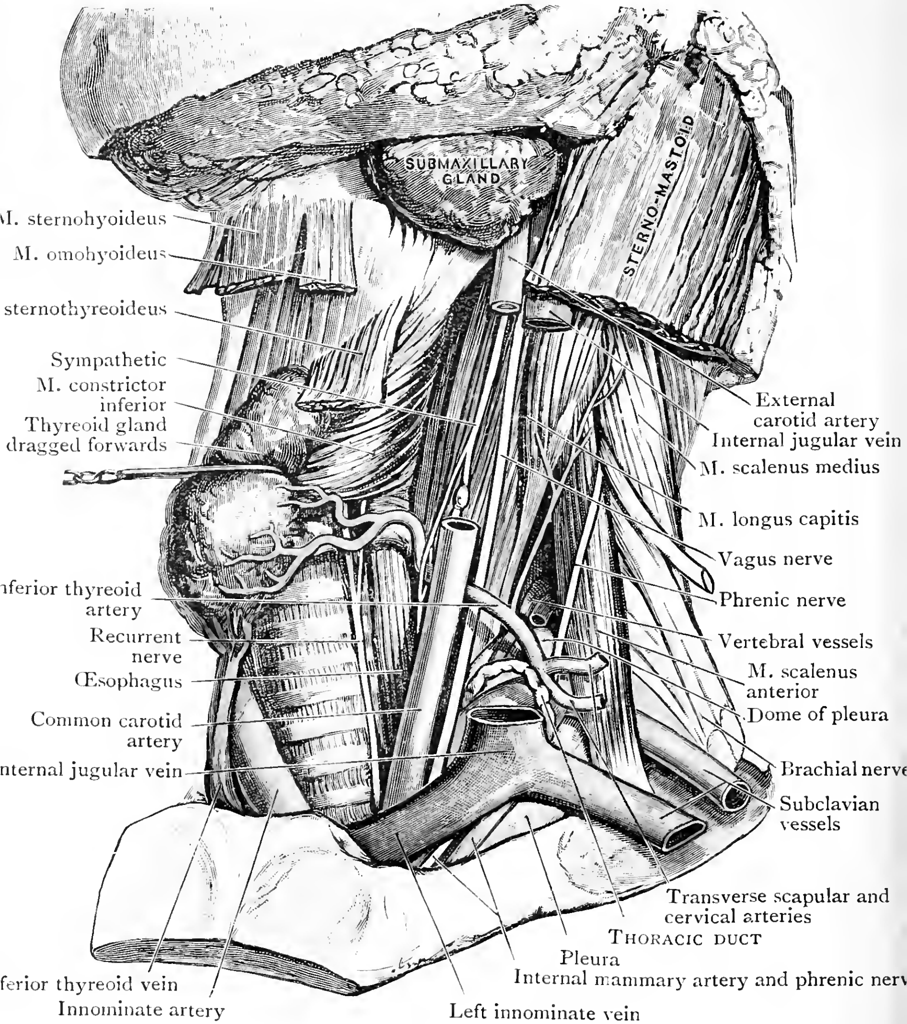

FIG. 55.—Deep Dissection of the Root of the Neck on the Left Side to show the Dome of the Pleura and the relations of the Terminal Part of the Thoracic Duct. The sterno-mastoid and the depressors of the hyoid and larynx have been removed.

subclavian artery were examined during the dissection of the posterior triangle (p. 37). The relations of the first and second parts must now be studied. On the right side, a small portion of the first part is already exposed between the lower

end of the internal jugular vein and the common carotid artery; the remainder can be seen if the internal jugular vein is drawn aside. On the left side, the first part of the artery is concealed by the commencement of the innominate vein, which must be pushed aside. On both sides, the second part of the artery lies posterior to the scalenus anterior, which must be left in position.

The subclavian artery is the first portion of the great arterial trunk which carries blood for the supply of the upper extremity. It arises differently on the two sides of the body. On the *right side*, it takes origin, behind the sterno-clavicular joint, as a terminal branch of the innominate artery. On the *left side*, it arises from the aortic arch, in the superior mediastinum. In both cases, it takes an arched course laterally across the root of the neck, posterior to the scalenus anterior and on the anterior surface of the cervical dome of pleura, a short distance below its summit. At the outer border of the first rib it becomes the axillary artery.

For descriptive purposes the artery is divided into three parts. The *first part* extends from the origin of the vessel to the medial margin of the scalenus anterior; the *second portion* lies posterior to that muscle; and the *third part* extends from the lateral border of the scalenus anterior to the outer border of the first rib.

First Part.—Owing to the difference of origin, the relations of the first portion of the subclavian artery are not the same on the two sides of the body. The first part of the *right subclavian* extends obliquely upwards and laterally, and at its termination at the medial margin of the scalenus anterior it has reached a point above the level of the clavicle. It is placed very deeply. Anteriorly, it is covered by the skin, superficial fascia, platysma, deep fascia, and three muscular strata—viz., the clavicular origin of the sterno-mastoid, the sterno-hyoid, and the sterno-thyreoid. Three veins and some nerves are placed anterior to it. At the medial margin of the scalenus anterior it is crossed by the internal jugular and vertebral veins, whilst the anterior jugular vein, as it passes laterally under cover of the sterno-mastoid, is separated from it by the sterno-hyoid and sterno-thyreoid muscles. The nerves which cross anterior to it are the vagus, a loop from the sympathetic (ansa subclavia), and in some cases cardiac branches of the vagus and sympathetic as they run to the

thorax. At the lower margin of the artery the vagus nerve gives off its recurrent branch.

The cervical dome of the pleura is both below and posterior

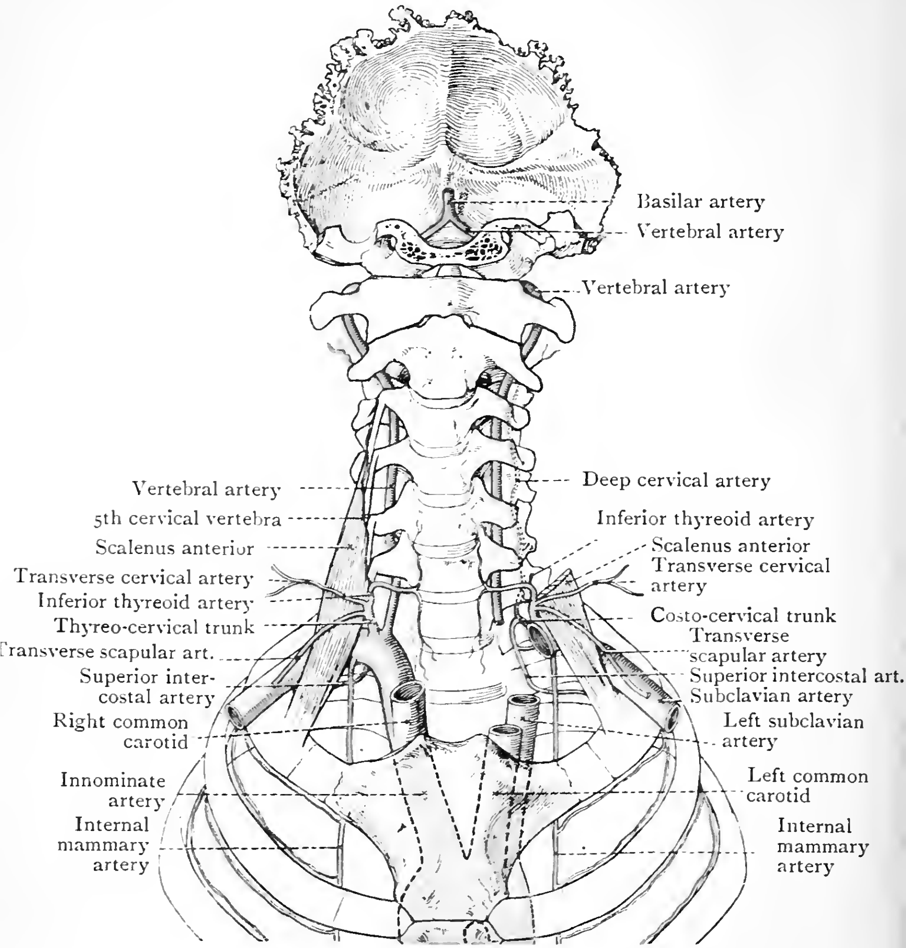

FIG. 56.—Diagram of Subclavian Arteries and their branches.

to the artery, and the recurrent branch of the vagus nerve hooks round below and ascends posterior to it.[1]

On the *left side*, the first part of the subclavian ascends almost vertically from its origin from the aortic arch, and,

[1] If the lung has been removed by the dissector of the thorax the lower and posterior relations should be verified by examination from the thoracic side.

reaching the root of the neck, it curves laterally across the dome of the pleura to the medial margin of the scalenus anterior. The relations of the cervical part are somewhat different from those on the right side. The same fascial and muscular layers, and the same nerves and veins, are anterior to it. Owing to its different direction, however, the nerves and veins are placed more or less parallel to it. Three additional relations are established—viz., the phrenic nerve and the left innominate vein lie anterior to it; and the thoracic duct first passes upwards in relation to its medial or right side, and then arches over it to reach the angle of junction between the subclavian and internal jugular veins (Fig. 55).

The recurrent nerve on the left side hooks round the arch of the aorta, and lies to the medial side of the subclavian artery.

Second Part.—The second portion of the subclavian artery forms the highest part or summit of the arch, and rises from half an inch to an inch above the level of the clavicle.

In that part of its course the vessel has not so many superficial relations. *Anteriorly*, it is covered by—(1) skin; (2) superficial fascia and platysma; (3) deep fascia; (4) clavicular head of the sterno-mastoid; (5) scalenus anterior. The phrenic nerve on the right side is also an anterior relation, but it is separated from the artery by the medial margin of the scalenus anterior. *Posteriorly and inferiorly*, the vessel is in relation with the pleura, Sibson's fascia intervening. The subclavian vein lies at a lower level than the artery and on an anterior plane, and is separated from it by the scalenus anterior.

The *third part* of the subclavian artery is described on p. 41.

Branches of the Subclavian Artery.—Four branches spring from the subclavian trunk (Fig. 56). Three take origin, as a general rule, from the first part of the artery, and one from the second part. They are—

From the *first part.*	1. Vertebral.	
	2. Thyreo-cervical.	Inferior thyreoid. Transverse cervical. Transverse scapular.
	3. Internal mammary.	
From the *second part.*	Costo-cervical.	Superior intercostal. Deep cervical.

In a great number of cases a branch of considerable size springs from

the third part of the subclavian artery. In some cases it is the descending branch of the transverse cervical, which then arises directly from the subclavian. In other cases it is the transverse scapular artery.

Arteria Vertebralis.—The vertebral artery is the first branch of the subclavian. It springs from the upper and posterior aspect of the trunk, about 6.2 mm. (a quarter of an inch) from the medial margin of the scalenus anterior, on the right side, and from the point where the vessel reaches the root of the neck, on the left side. Only a small portion of it is seen in the present dissection. It proceeds upwards, in the interval between the longus colli and the scalenus anterior muscles, posterior to the common carotid, and disappears into the foramen transversarium of the sixth cervical vertebra. It is placed very deeply, and is covered anteriorly by its companion vein and the common carotid artery. Numerous large sympathetic twigs accompany it.

The vertebral artery on the *left side* is posterior to the internal jugular vein and the common carotid artery, and it is crossed by the thoracic duct.

The *vertebral vein* issues from the aperture in the transverse process of the sixth cervical vertebra. It passes downwards, antero-lateral to its companion artery, and posterior to the internal jugular vein, to open into the posterior aspect of the commencement of the corresponding innominate vein. Near its termination it crosses the subclavian artery. It receives the *deep cervical* and the *anterior vertebral veins*.

Truncus Thyreocervicalis (O.T. **Thyroid Axis**).—The thyreo-cervical trunk is a short wide vessel, which arises from the anterior aspect of the subclavian artery, close to the medial margin of the scalenus anterior, and under cover of the internal jugular vein. It lies between the phrenic and vagus nerves, and almost immediately breaks up into its three terminal branches—viz., the inferior thyreoid, the transverse scapular, and the transverse cervical.

Arteria Thyreoidea Inferior.—The inferior thyreoid artery takes a sinuous course to reach the thyreoid gland. First, it ascends for a short distance along the medial border of the scalenus anterior, and under cover of the internal jugular vein; then, at the level of the cricoid cartilage, it turns suddenly medialwards and passes posterior to the vagus, the sympathetic, and the common carotid artery, to reach the posterior border of the thyreoid gland. There it gives off

branches to the pharynx and larynx, and then descends along the posterior border of the thyreoid gland, distributing branches to its substance and to the trachea and the œsophagus.

The following branches will be noticed arising from the inferior thyreoid artery :—

1. Ascending cervical.	5. Œsophageal.
2. Inferior laryngeal.	6. Glandular.
3. Tracheal.	7. Muscular.
4. Pharyngeal.	

Arteria Cervicalis Ascendens.—The ascending cervical artery (Fig. 51) is a small but constant vessel which runs upwards, in the interval between the scalenus anterior and longus capitis, and gives branches to the muscles in front of the vertebral column. It also gives off *spinal branches*, which enter the vertebral canal upon the spinal nerves, and anastomose with branches from the vertebral artery. The ultimate distribution of the spinal branches has been noticed already (p. 79).

Arteria Laryngea Inferior.—The inferior laryngeal artery is a small vessel which accompanies the recurrent nerve to the larynx.

The *tracheal*, *œsophageal*, and *pharyngeal branches* supply the trachea, the gullet, and the pharynx. They are of small size, and anastomose with the bronchial and œsophageal branches of the thoracic aorta. The *glandular branches* are usually two in number. One ascends upon the posterior aspect of the corresponding lobe of the thyreoid gland, whilst the other is given to its base or lower end. They inosculate with the corresponding vessels of the opposite side, and also with the branches of the superior thyreoid artery. The *muscular branches* are a series of irregular twigs given to neighbouring muscles.

Venæ Thyreoideæ Inferiores.—The inferior thyreoid veins do not run in company with the arteries of the same name. Each is a comparatively large vessel which comes from the corresponding lobe and the isthmus of the thyreoid gland, and descends upon the trachea under cover of the sterno-thyreoid muscle. The veins of both sides enter the thorax, and frequently unite to form a short common stem, which opens into the left innominate vein. In other cases, however, the right vein opens separately into the angle of union between the two innominate veins. Both veins, as they proceed

downwards, receive tributaries from the larynx, trachea and œsophagus.

The *anterior vertebral vein* accompanies the ascending cervical artery, and opens into the vertebral vein as it issues from the foramen transversarium of the sixth cervical vertebra.

Arteriæ Transversæ Scapulæ et Colli.—The transverse scapular and the transverse cervical arteries have already been examined in the greater part of their courses (p. 34). After taking origin from the thyreo-cervical trunk, they both pass laterally, across the scalenus anterior muscle and the phrenic nerve, under cover of the clavicular head of the sterno-mastoid. The *transverse scapular* crosses the anterior scalene muscle close to its insertion, immediately above the subclavian vein; the *transverse cervical* is placed at a slightly higher level.

The *transverse scapular* and *transverse cervical veins* have already been seen joining the external jugular vein (p. 40).

Arteria Mammaria Interna.—The internal mammary artery springs from the lower and anterior aspect of the subclavian, directly below the thyreo-cervical trunk. It passes downwards to reach the thorax, lying upon the anterior surface of the pleura, and posterior to the medial end of the clavicle and the medial end of the subclavian vein. As it lies posterior to the subclavian vein the phrenic nerve passes from its lateral to its medial side, either anterior or posterior to it. In the neck the internal mammary artery is not accompanied by a vein.

Truncus Costocervicalis.—On the right side the costo-cervical trunk takes origin from the posterior aspect of the second portion of the subclavian artery, close to the medial border of the scalenus anterior. To bring it into view the subclavian artery must be dislodged from its position. On the left side, however, it proceeds, as a rule, from the first part of the parent trunk. It is a short trunk which passes upwards and backwards, over the apex of the pleura, to the neck of the first rib, where it divides into the *deep cervical artery* and the *superior intercostal artery*.

If the lung is removed from the thorax, the dissector should take the opportunity of examining this artery from the thoracic aspect.

Arteria Cervicalis Profunda.—The deep cervical artery passes dorsally, and disappears from view between the

transverse process of the seventh cervical vertebra and the neck of the first rib. It has been already noticed in the dissection of the back of the neck (p. 67).

The *deep cervical vein* is a large vessel. It joins the vertebral vein.

Arteria Intercostalis Suprema.—The superior intercostal artery turns downwards, anterior to the neck of the first rib, between the first thoracic nerve and the first thoracic ganglion of the sympathetic trunk. It gives a posterior intercostal branch to the first space and ends as the posterior intercostal artery of the second space (Fig. 56).

Vena Subclavia.—The subclavian vein is the continuation of the axillary vein into the root of the neck. It begins at the outer border of the first rib, and arches medially across the anterior surface of the lower end of the scalenus anterior. At the medial margin of that muscle, and posterior to the sternal end of the clavicle, it unites with the internal jugular vein to form the innominate vein. In connection with the subclavian vein note: (1) that the arch which it forms is not so pronounced as the arch of the corresponding artery; (2) that throughout its whole course it lies at a lower level, and upon a plane anterior to the artery; and (3) that it is separated from the artery by the scalenus anterior and the phrenic nerve. In the whole of its course the vein lies posterior to the clavicle.

The sheath of the subclavian vein is attached to the posterior surface of the costo-coracoid membrane. The relation is of some practical importance; for, on account of it, a forward movement of the clavicle drags upon the vein, and in cases where the vessel is wounded there is always a danger of air being sucked into the vein by such a movement.

The *tributary* of the subclavian vein is the external jugular vein, which joins it at the lateral margin of the scalenus anterior.

Ductus Thoracicus et Ductus Lymphaticus Dexter.—The *thoracic duct* is the vessel by means of which the chyle, and the lymph derived from by far the greater part of the body, are poured into the venous system on the left side (p. 147). Its terminal or cervical portion is displayed in the dissection of the neck. It is a small, thin-walled vessel, frequently mistaken for a vein, which enters the root of the neck at the left margin of the œsophagus. It is there that it should be sought for. At the level of the seventh cervical vertebra it

arches laterally and forwards, and then downwards, above the apex of the pleura, and it enters the innominate vein in the angle of the union of the internal jugular vein with the

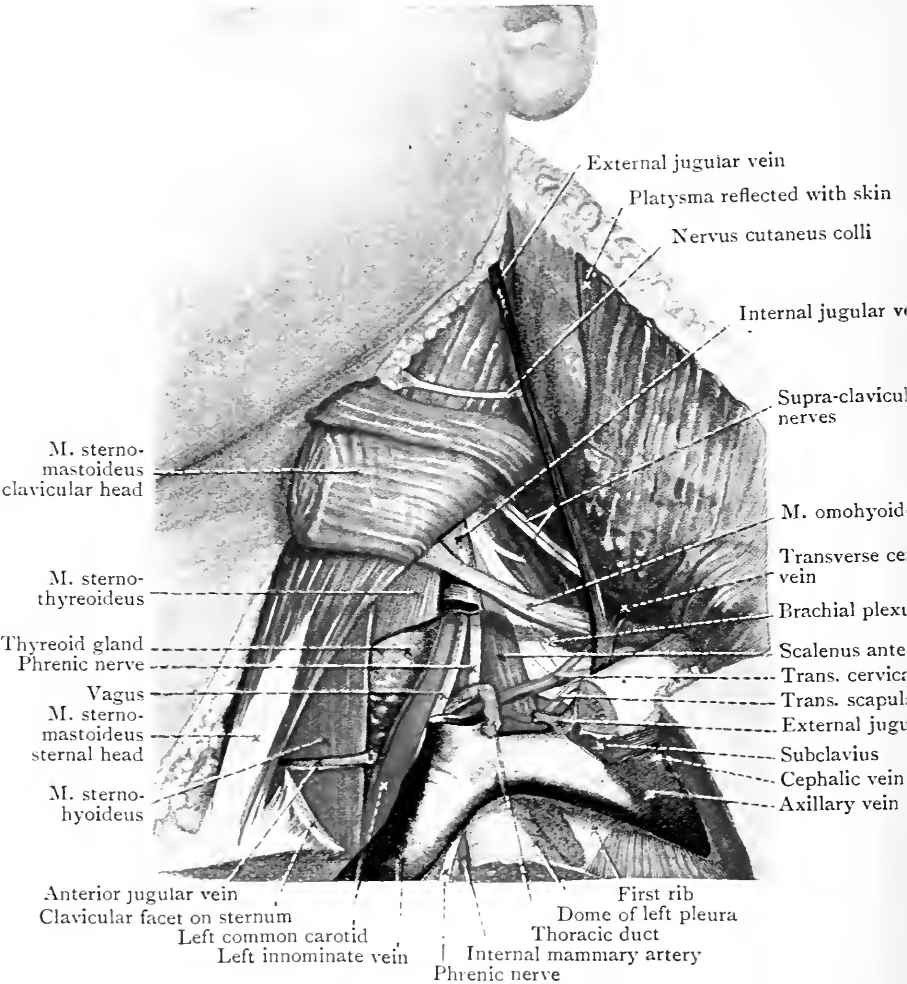

FIG. 57.—Deep Dissection of the Root of the Neck on the Left Side to show the Dome of the Pleura and the relations of the Terminal Part of the Thoracic Duct. Parts of the sterno-mastoid and the sterno-thyreoid have been removed.

subclavian. As the thoracic duct courses laterally it lies at a higher level than the subclavian artery, and passes posterior to the common carotid artery, the vagus nerve, and the internal jugular vein; and anterior to the vertebral artery and vein and the thyreo-cervical trunk or its inferior thyreoid branch;

and as it runs downwards to its termination it is separated from the scalenus anterior by the transverse cervical and transverse scapular arteries and the phrenic nerve. Further, as it approaches the point at which it ends, it lies anterior to the first part of the subclavian artery (Figs. 55, 56).

A valve composed of two semilunar segments guards its entrance into the innominate vein.

The *right lymph duct* is the corresponding vessel on the right side, but it is a comparatively insignificant channel which conveys lymph from a much more restricted area. It commences in the root of the neck, where it is formed by the union of the broncho-mediastinal trunk with the subclavian and jugular lymphatic trunks of the right side. It terminates in the commencement of the innominate vein by opening into it in the angle of union of the subclavian and internal jugular veins. As in the case of the thoracic duct, its orifice is guarded by a double valve. Through the broncho-mediastinal trunk it receives lymph from the intercostal glands which lie in the upper intercostal spaces of the right side, and from the thoracic visceral lymph glands of the right side; and, through the right subclavian and jugular lymph trunks, lymph is poured into it from the right upper extremity and the right side of the head and neck, respectively. It constitutes, therefore, the main lymph drain for the following districts: (1) right upper limb; (2) right side of the head and neck; (3) upper part of right thoracic wall; (4) right side of diaphragm and upper surface of liver; (5) thoracic viscera on right side of median plane, viz., right side of the heart and pericardium and the right lung and pleura. But not uncommonly the broncho-mediastinal, the right jugular and subclavian lymph trunks open separately into the internal jugular, the subclavian or the innominate vein.

Cervical Pleura.—The pleural sac of each side, with the apex of the corresponding lung, projects upwards into the root of the neck, and the dissector should now examine the height to which it rises, and the connections which it establishes. Its height, with reference to the first pair of costal arches, varies in different subjects. In some cases it extends upwards for two inches above the sternal end of the first rib; in others, for not more than one inch. The differences depend on the degree of obliquity of the thoracic inlet.

Posteriorly, in the majority of cases, the apex of the pleura corresponds, in level, with the neck of the first rib. It forms a dome-like roof for each side of the thoracic cavity, and is strengthened by a fascial expansion (frequently termed *Sibson's fascia*), which covers it completely, and is attached, on the one hand, to the transverse process of the seventh cervical

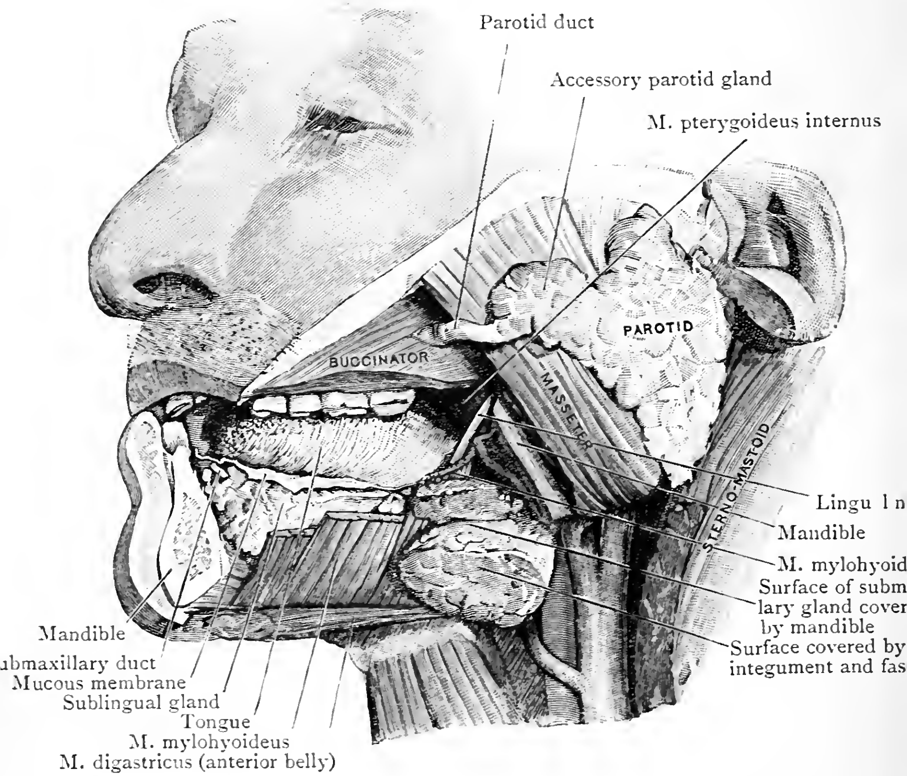

FIG. 58.—Dissection of the Parotid, Submaxillary, and Sublingual Glands.

vertebra, and, on the other, to the inner margin of the first rib.

Note that it is in relation with: (1) the scalenus anterior; (2) the scalenus medius; (3) the subclavian artery; (4) the vertebral artery; (5) the costo-cervical trunk; (6) the superior intercostal artery; (7) the internal mammary artery; (8) the innominate vein; (9) the vertebral vein; (10) the subclavian vein; (11) the vagus nerve; (12) the phrenic nerve; (13) the recurrent nerve, on the right side; (14) the first thoracic

nerve; (15) the first thoracic ganglion of the sympathetic; (16) the ansa subclavia (Vieussenii).

The scalenus anterior covers the antero-lateral part of the dome, separating it from the subclavian vein, which ends at the medial border of the muscle. Immediately above the vein the subclavian artery crosses the dome, below its apex. The internal mammary artery descends from the subclavian, passes posterior to the subclavian vein, and is crossed, as it lies behind the vein, by the phrenic nerve, which passes in some cases anterior to, and in others posterior to the artery. The costo-cervical trunk ascends from the subclavian and crosses the apex of the dome; its superior intercostal branch descends, posterior to the apex, between the first intercostal nerve on the lateral side, and the first thoracic sympathetic ganglion on the medial side. The vagus nerve descends anterior to the medial part of the subclavian artery, and, on the right side, its recurrent branch turns round the lower border of the artery; the ansa subclavia lies to the lateral side of the recurrent nerve.

PAROTID REGION.

It is not possible to examine the relations of either the whole of the internal jugular vein or the external carotid artery, or the whole of the cervical portion of the internal carotid, until the parotid gland has been removed, the infra-temporal and submaxillary regions have been dissected, and the posterior belly of the digastric and the styloid process have been detached and displaced forwards. It is important, however, that the internal jugular vein should be retained in position whilst those parts of the dissection are being proceeded with; the dissector should therefore stitch the subclavian vein to the anterior surface of the scalenus anterior, and the lower part of the internal jugular vein to the first part of the subclavian artery, before proceeding to the study and removal of the parotid gland.

Glandula Parotis.—The parotid gland is wedged into a more or less triangular interval, the *parotid space*, which is bounded anteriorly by the posterior borders of the masseter, the ramus of the mandible, and the internal pterygoid, and postero-medially by the anterior border of the sterno-mastoid,

the mastoid process, the posterior belly of the digastric, the styloid process, and the stylo-hyoid muscle. The space extends upwards to the external acoustic meatus, and it is prolonged downwards into the carotid triangle, into which the lower extremity of the gland descends, for a short distance, beyond the angle of the mandible. The gland, however, is more extensive than the space and passes for a varying distance forwards, beyond the anterior border of the

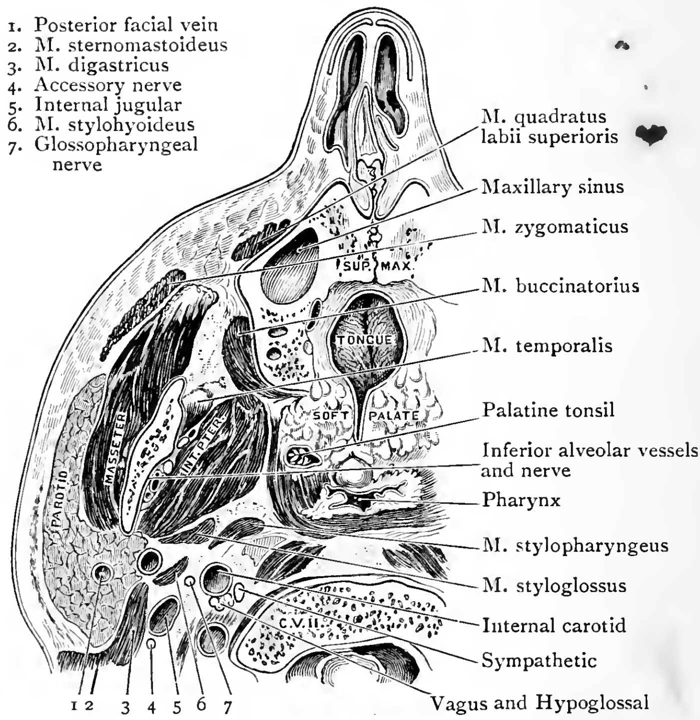

FIG. 59.—Transverse section through the Head at the level of the Hard Palate. It shows the relations of the parotid gland, etc.

space, over the superficial surface of the masseter (Figs. 4, 58).

In accordance with the position which it occupies the gland may be described as possessing four surfaces, two extremities, and four borders. The surfaces are superficial or lateral, postero-medial, antero-medial, and superior; the extremities, upper and lower; the borders, anterior, posterior, medial, and superior. The medial border separates the antero-medial from the postero-medial surface. The anterior and posterior borders separate the lateral surface from the

antero-medial and postero-medial surfaces, respectively. The upper border circumscribes the upper surface and intervenes between it and the other three surfaces.

The *superficial surface* is irregular in outline (Figs. 4 and 60). It is covered by skin, superficial fascia, platysma and risorius, and deep fascia. Embedded in it are a few superficial parotid lymph glands, which receive lymph from the anterior part of the scalp, from the face, above the level of the mouth, and from the lateral surface of the auricle. Posteriorly, it is in relation with the mastoid process and the anterior

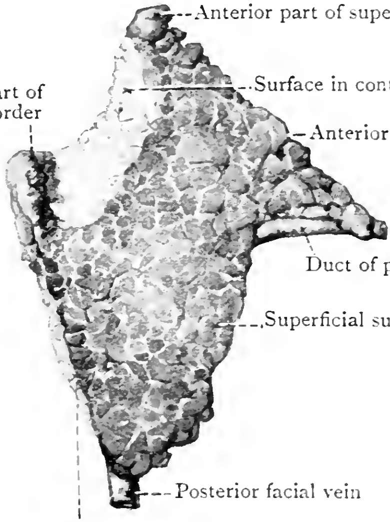

FIG. 60.—Parotid Gland, lateral view.

border of the sterno-mastoid muscle. Above, it touches the posterior part of the lower border of the zygoma and the lower surface of the external meatus.

From beneath the part in contact with the zygoma emerge the auriculo-temporal nerve, the temporal branches of the facial nerve, and the superficial temporal artery, on their way to the scalp; and the posterior facial vein disappears under cover of it. Its lower extremity, which is wedged between the angle of the mandible and the anterior border of the sterno-mastoid, is usually in contact with one of the upper deep cervical glands, whilst the cervical branch of the facial nerve, the posterior facial vein, and a communication to the external jugular vein emerge from it; the former two pass downwards and forwards, and the latter one passes downwards and backwards.

From under cover of the anterior border, which rests upon the masseter, the duct of the gland (Stensen's), the transverse facial artery, and the zygomatic, buccal, and mandibular branches of the facial nerve pass forwards; and the transverse facial vein disappears under cover of it.

The *duct of the parotid gland* (Stensen's), after appearing from under cover of the anterior border of the gland, runs forwards, across the masseter, at the level of a line drawn from the lobule of the auricle to a point situated midway between the red margin of the upper lip and the ala of the nose. At the anterior border of the masseter it turns inwards, at right angles to its former course, and after piercing the sucking pad of fat, the buccinator fascia, the buccinator muscle and the mucous membrane of the vestibule of the mouth, it opens into the vestibule, on the apex of a papilla, opposite the second molar tooth of the maxilla.

Immediately in front of the anterior border of the gland, below the zygoma and above the duct, lies a small separated portion of the gland substance called the *accessory parotid*; its duct opens into the main duct.

Dissection.—The gland must be removed piecemeal as the structures which pass through it are dissected out. The facial nerve and its branches are the most superficial structures in the substance of the parotid; therefore they must be dissected first. Trace the terminal branches backwards into the gland until they join the main divisions, which are the *upper* and the *lower*. The temporal and zygomatic branches spring from the upper division; the buccal, mandibular, and cervical spring from the lower division. Follow the divisions backwards, across the posterior facial vein, to their union with the trunk of the nerve, which pierces the postero-medial surface of the gland; then trace the trunk, across the root of the styloid process, to the stylo-mastoid foramen, and secure the branch which springs from it to supply the posterior belly of the digastric and the stylo-hyoid muscles, and the posterior auricular branch. As the trunk of the nerve is being cleaned the posterior auricular branch of the external carotid artery will probably be exposed, passing upwards and backwards, along the upper border of the posterior belly of the digastric, to the back of the external meatus, and crossing either superficial or deep to the nerve. Next, remove the deeper parts of the gland and expose the posterior facial vein, descending towards the angle of the mandible. It receives the transverse facial and the internal maxillary veins, and it gives off a communicating branch to the external jugular vein; then it passes out of the lower end of the gland and unites with the anterior facial vein to form the common facial vein. Deep to the veins will be found the upper end of the external carotid artery dividing into its superficial temporal and internal maxillary branches;

and the transverse facial and middle temporal offsets of the superficial temporal will also be displayed.

When the remains of the deeper part of the gland have been removed, the styloid process with the origin of the stylo-hyoid muscle, and the posterior belly of the digastric will be exposed; and the internal jugular vein and the internal and external carotid arteries will be seen disappearing under cover of the digastric. If the occipital artery lies at its lower level, it also will be noted as it runs upwards and backwards, along the lower border of the digastric, crossing superficial to the two large vessels, and to the accessory nerve, which emerges from under cover of the digastric and passes downwards and backwards across the internal jugular vein.

The dissector should now obtain a gland which has been removed uninjured from the parotid space, or a cast of a gland, and proceed to study the relations of the upper end and the postero-medial and antero-medial surfaces.

The *upper surface* presents a deep concavity which is usually separable into a larger lateral part which lies in contact with the cartilaginous part of the external meatus, and a smaller medial part which touches the bony wall of the meatus (Fig. 61). The anterior boundary of the upper end forms a sharp ridge, which lies in the narrow interval between the capsule of the mandibular articulation and the front of the external meatus.

The *postero-medial surface* is marked by a series of depressions which correspond with the structures in the postero-medial boundary of the parotid space. Above is a shallow depression corresponding with the anterior border of the mastoid process, and, below the latter, a groove caused by the anterior border of the sterno-mastoid. More medially is a shallow depression due to the posterior belly of the digastric and the stylo-hyoid, and, still more medially and at a higher level, a sulcus which corresponds with the position of the styloid process. Below the level of the digastric groove the postero-medial surface covers portions of the internal jugular vein and the internal and external carotid arteries (Fig. 61). The communication to the external jugular vein, the posterior facial vein, and the cervical branch of the facial nerve emerge from that part of the surface. Immediately above the digastric groove, close to the medial border, the external carotid artery enters the gland; and, directly lateral to the upper end of the groove for the styloid process, the facial nerve passes into the gland substance (Fig. 62). The dissector should note that

the postero-medial surface of the gland is separated from the upper parts of the internal jugular vein and the internal carotid artery, and from the last four cerebral nerves by the posterior belly of the digastric, the styloid process and the muscles attached to it.

The *medial border* of the gland lies in the angle between the postero-medial and the anterior boundaries of the parotid space, where the styloid process, the stylo-hyoid muscle, and the posterior belly of the digastric disappear under cover of the posterior border of the internal pterygoid muscle; and

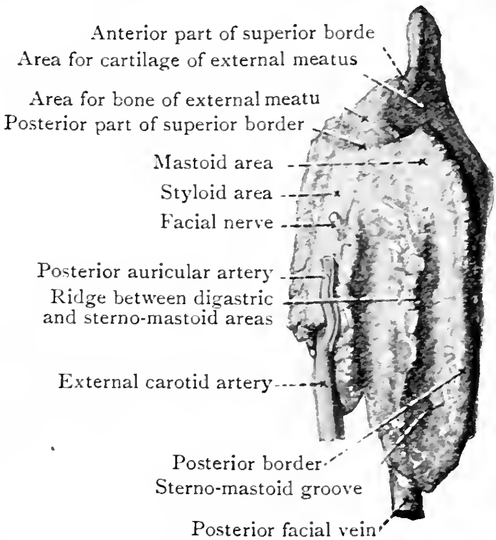

FIG. 61.—Parotid Gland, postero-medial aspect.

from it a process, *the pterygoid lobe*, usually projects forwards, for a short distance, between the internal pterygoid and the medial surface of the ramus of the mandible. Through the base of that process the external carotid passes from the postero-medial to the antero-medial surface of the gland.

The antero-medial surface. — The medial part of the antero-medial surface is directed forwards and lies in relation with the lower part of the posterior border of the internal pterygoid, the stylo-mandibular ligament, and the posterior border of the ramus of the mandible. The more lateral part is directed medially and rests against the lateral surface of the masseter. The antero-medial surface is pierced (1) by the external carotid artery, (2) the posterior facial and the internal

maxillary veins, (3) all the terminal branches of the facial nerve except the cervical, and (4) by the duct of the gland.

As the dissector examines the parotid space he will note that as the external carotid disappears under cover of the posterior belly of the digastric it is placed so far forwards that it is also under cover of the posterior border of the mandible; and it does not emerge from under cover of the mandible until it reaches the level of the neck of the bone, where it appears on the antero-medial surface of the gland and divides into its two terminal branches. Further, he will now readily recognise the impossibility of studying

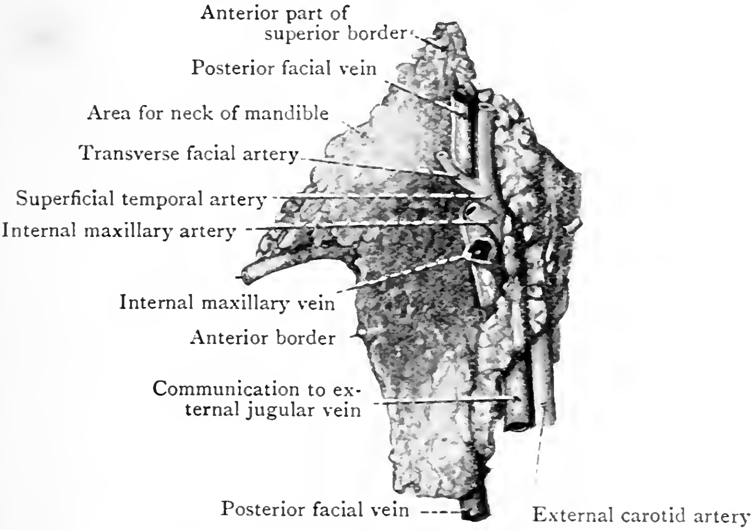

FIG. 62.—Parotid Gland, antero-medial aspect.

the upper end of the cervical part of the internal carotid, the upper part of the internal jugular vein, and the last four cerebral nerves, until he is in a position to reflect the posterior belly of the digastric and the styloid process; and as both of them are, to a certain extent, under cover of the mandible it is obvious that the mandible must be removed. That will be done during the dissection of the temporal and infratemporal regions, which must now be proceeded with.

TEMPORAL AND INFRATEMPORAL REGIONS.

Fascia Temporalis.—The temporal fascia is a strong, glistening membrane which is stretched over the temporal fossa, binding down the temporal muscle. Its upper margin

is attached to the upper temporal line on the lateral aspect of the parietal bone, and anteriorly to the temporal line of the frontal bone. As it approaches the zygomatic arch, it splits into two laminæ, which are separated from each other by a narrow interval filled with fat. The two laminæ are attached one to the upper border of the zygomatic arch and the posterior border of the zygomatic bone, and the other to the medial surfaces of those two portions of bone. They can readily be demonstrated by dividing the superficial layer close to its attachment, and throwing it upwards; by the handle of the knife the attachment of the deep layer can then be made out. In the upper part of its extent, the temporal fascia is comparatively thin and the fibres of the subjacent muscle may be seen shining through it; below, it is thicker, and owing to the fat which is interposed between its laminæ, it is perfectly opaque. It is pierced immediately above the posterior part of the zygomatic arch by the middle temporal branch of the superficial temporal artery and by the middle temporal vein (p. 48).

Musculus Masseter.—The masseter is a thick quadrate muscle which covers the ramus of the mandible. Its fibres are arranged in two sets—a superficial and a deep. The *superficial part* of the muscle arises from the anterior two-thirds of the lower border of the zygomatic arch, and its fasciculi are directed downwards and backwards. The *deep part* springs from the whole length of the medial aspect of the zygomatic arch, and also from the posterior third of its lower border. Its fibres proceed downwards. Only a small piece of the upper and posterior part of the latter portion appears on the surface. The masseter is inserted into the lateral surface of the ramus of the mandible, over an area which extends downwards to the angle, and upwards so as to include the lateral aspect of the coronoid process. The masseter raises the mandible and helps to protract it. The deeper fibres which run downwards and forwards when the mandible is protracted help to retract the protracted bone. The nerve of supply is derived from the mandibular division of the trigeminal nerve.

Dissection.—Turn the upper part of the posterior margin of the masseter forwards and secure its nerve and artery of supply which pass to it through the incisura mandibularis, behind the tendon of the temporal muscle. To display the temporal muscle,

make the following dissection. Divide the deep part of the temporal fascia along the upper border of the zygomatic arch and remove it. The middle temporal artery and the zygomatico-temporal nerve, which pierce it, must be disengaged from it and preserved. Divide the zygomatic arch, behind and in front of the masseter, and throw the arch, with the attached masseter, downwards. As that is being done cut the artery and nerve of supply out of the masseter muscle, leaving a small portion of the muscular substance attached to them so that they may be identified at later stages of the dissection. First make use of the saw, and then complete the division by means of the bone forceps. The posterior cut should be made immediately anterior to the articular tubercle which lies in front of the mandibular (O.T. glenoid) fossa and the head of the mandible; the anterior cut must extend obliquely through the zygomatic bone, from the extreme anterior end of the upper margin of the arch, downwards and forwards to the point where the lower margin meets the zygomatic process of the maxilla. When the division is completed, and the nerve and artery to the masseter are detached, the whole arch and the attached masseter may be readily thrown downwards towards the angle of the mandible. The fleshy origin of the deep portion of the masseter from the medial surface of the zygomatic arch can then be seen. The dissection is frequently complicated by a number of fibres from the temporal muscle joining the deep part of the masseter. Leave the masseter attached to the angle of the mandible, and clean the temporal muscle.

Musculus Temporalis.—The temporal muscle is fan-shaped. It arises from the whole extent of the temporal fossa, from the lower temporal line to the infratemporal crest on the great wing of the sphenoid. It receives additional fibres also from the deep surface of the temporal fascia. From their broad origin the fasciculi converge towards the coronoid process of the mandible. The anterior fibres descend vertically, the posterior fibres at first pursue a nearly horizontal course, whilst the intermediate fasciculi proceed with varying degrees of obliquity. A tendon is developed upon its superficial aspect, near its insertion, and the tendon is inserted into the summit and anterior edge of the coronoid process. The deep part of the muscle remains fleshy, and gains insertion to the medial surface of the coronoid process by an attachment which reaches as low down as the point where the anterior margin of the ramus merges into the body of the mandible. The insertion cannot be fully examined at present; it will be dealt with later. The temporal muscle raises the mandible and retracts it. It is supplied by a branch of the mandibular division of the trigeminal nerve.

Dissection.—Detach the coronoid process from the mandible,

and turn it upwards with the attached temporal muscle. A very oblique cut is required; it should extend from the centre of the incisura mandibulæ above, downwards and forwards, to the point where the anterior margin of the ramus meets the body of the mandible. First use the saw, and then complete the division with the bone forceps. The *buccinator nerve* (O.T. *long buccal*) and its companion *artery* are in a position of danger during this dissection, and must be carefully guarded. They proceed downwards and forwards, under cover of the lower part of the temporal muscle, and not infrequently the nerve traverses the substance of the muscle. The coronoid process and the temporal muscle must be thrown well upwards, and the muscular fibres must be separated, by the handle of the knife, from the bone forming the lower part of the temporal fossa, in order that *deep temporal nerves* and *arteries* may be exposed, as they ascend between the cranial wall and the muscle. At this stage the *middle temporal artery* will also be exposed as it extends upwards upon the squamous part of the temporal bone. If it is injected branches will be found passing from it to the temporal muscle. The zygomatico-temporal nerve should now be traced to the point where it emerges from the minute aperture on the temporal surface of the zygomatic bone. At that point it lies under cover of the temporal muscle.

The infratemporal region (O.T. pterygo-maxillary) may now be fully opened up by removing a portion of the ramus of the mandible. Two horizontal cuts must be made—one through the neck of the mandible, and the other immediately above the level of the mandibular (O.T. inferior dental) foramen. To find the level of the foramen, thrust the handle of the knife between the ramus and the subjacent soft parts, and carry it downwards. Its progress will soon be arrested by the entrance of the inferior alveolar vessels and nerve into the foramen, and the lower border of the instrument will correspond with the line along which the bone should be cut. Both incisions should be made with the saw, until the lateral table of the bone is cut through, and then the bone forceps may be employed to complete the division. Lastly, remove the fat and areolar tissue.

When the fat and areolar tissue are removed, the pterygoid muscles will come into view. The *external pterygoid* extends backwards to the neck of the mandible. The *internal pterygoid*, embracing the anterior part of the external pterygoid muscle between its two heads of origin, proceeds downwards and backwards upon the deep surface of the ramus of the mandible. The great blood vessel of the space—the *internal maxillary artery* —passes forwards upon (frequently under cover of) the lower head of the external pterygoid muscle. The *nerves* of the region also will be found in close relationship to the same muscle. Emerging from between its upper border and the cranial wall, at the level of the infratemporal crest, are the *masseteric* and the *posterior deep temporal nerves* posteriorly, and the *anterior deep temporal nerve* anteriorly; appearing from under cover of its lower border are the *inferior alveolar nerve*, which descends to the alveolar foramen of the mandible, and more anteriorly the *lingual nerve*; whilst emerging between the two heads of the external pterygoid is the *buccinator nerve*. The *spheno-*

mandibular ligament also will be seen. It is the thin strip of membrane which lies medial to the inferior alveolar nerve.

Musculus Pterygoideus Externus.—The external pterygoid arises in the infratemporal fossa by two heads, an upper and a lower. The *upper head*, which is the smaller, springs from the infratemporal ridge and infratemporal surface of the great wing of the sphenoid; the *lower head* takes origin from the

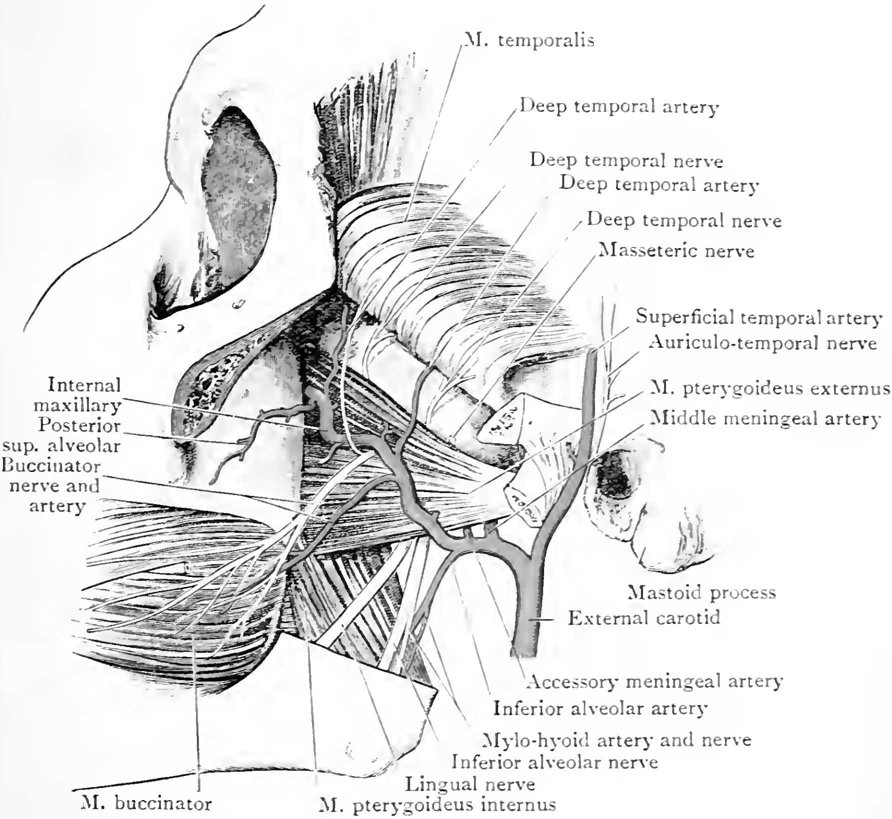

FIG. 63.—Dissection of the Infratemporal Region.

lateral surface of the lateral pterygoid lamina. The muscle diminishes in width as it passes backwards, and it is inserted into the fovea on the anterior surface of the neck of the mandible, and also into the capsule of the mandibular articulation at the level of the anterior margin of the articular disc of the joint. It protrudes and depresses the mandible and pulls it towards the opposite side. It is supplied by a branch of the mandibular division of the trigeminal nerve.

Musculus Pterygoideus Internus.—The internal pterygoid also is bicipital at its origin, and its two heads embrace the origin of the lower head of the external pterygoid. The *superficial* and smaller *head* of the internal pterygoid springs from the lower and posterior part of the tuberosity of the maxilla behind the last molar tooth, and also from the adjoining lateral surface of the pyramidal process (O.T. tuberosity) of the palate bone; the *deep head*, hidden by the external pterygoid, arises in the pterygoid fossa from the medial surface of the lateral pterygoid lamina, and from the posterior surface of the pyramidal process of the palate bone which appears between the two pterygoid laminæ. The two heads of the muscle unite at the lower margin of the anterior part of the external pterygoid, and the fibres proceed downwards with a postero-lateral inclination, and gain insertion into the angle of the mandible, and into the lower and posterior part of the medial aspect of the ramus as high as the mandibular foramen. The internal pterygoid raises the mandible, protrudes it, and pulls it towards the opposite side. It is supplied by a branch of the mandibular division of the trigeminal nerve.

Arteria Maxillaris Interna.—The internal maxillary artery is the larger of the two terminal branches of the external carotid artery. It takes origin immediately posterior to the neck of the mandible and passes forwards to the anterior part of the infratemporal fossa, where it disappears from view by dipping between the two heads of origin of the external pterygoid muscle and entering the pterygo-palatine fossa. It is divided into three parts, for convenience of description. The *first part* runs, horizontally, between the neck of the mandible and the spheno-mandibular ligament. It lies along the lower border of the posterior part of the external pterygoid muscle, and usually crosses the inferior alveolar nerve superficially. The *second part* extends obliquely upwards and forwards upon the lateral surface of the lower head of the external pterygoid muscle, under cover of the insertion of the temporal muscle. The *third part* dips between the two heads of the external pterygoid into the pterygo-palatine fossa (Fig. 63).

The arrangement described is that most frequently found, but it is not uncommon to find the second part of the artery lying in a deeper plane, viz. between the internal and external

pterygoid muscles. In that case the vessel makes a bend laterally, between the heads of the external pterygoid muscle before entering the pterygo-palatine fossa.

The *branches* of the internal maxillary artery are classified according to the portion of the vessel from which they spring. Only one branch of the third part, viz. the *posterior superior alveolar artery*, can be studied in this dissection. Those arising from the first and second parts are:—

From the First Part.	From the Second Part.
1. Arteria auricularis profunda.	1. Arteria masseterica.
2. Arteria tympanica.	2. Rami pterygoidei.
3. Arteria meningea media.	3. Arteriæ temporales profundæ.
4. Ramus meningeus accessorius.	4. Arteria buccinatoria.
5. Arteria alveolaris inferior.	

Arteria Auricularis Profunda.—The deep auricular artery is a small vessel which pierces the anterior wall of the external acoustic meatus to supply the skin which lines the meatus, and also the superficial part of the tympanic membrane.

Arteriæ Meningea Media et Tympanica Anterior.—The middle meningeal and the anterior tympanic branches pass upwards under cover of the external pterygoid muscle, and, therefore, cannot be fully studied until that muscle is reflected.

Arteria Alveolaris Inferior.—The inferior alveolar artery arises opposite the middle meningeal, and runs downwards, along the lateral surface of the spheno-mandibular ligament, to enter the mandibular foramen. It is generally accompanied by two venæ comites, and it is placed posterior to the inferior alveolar nerve. Just before entering the foramen, the inferior alveolar artery gives off the slender *mylo-hyoid branch*, which runs downwards and forwards, with the corresponding nerve, upon the deep aspect of the mandible, to the digastric triangle of the neck.

The branches from the second part are given off for the supply of the neighbouring muscles. The *Masseteric* passes horizontally, posterior to the temporal muscle, with the nerve of the same name, and has been seen entering the masseter muscle. The *Pterygoid Branches* are irregular twigs to the

pterygoid muscles. The *Deep Temporal Branches* are two in number—*anterior* and *posterior*; they pass upwards in the temporal fossa, between the bony wall of the cranium and the temporal muscle. They supply twigs to the temporal muscle, and they anastomose with the middle temporal artery. The *Buccinator Branch* accompanies the buccinator nerve, and is distributed to the buccinator muscle and the mucous membrane of the cheek. It anastomoses with the external maxillary (O.T. facial) artery.

Arteria Alveolaris Superior Posterior.—The posterior superior alveolar branch from the third part of the internal maxillary artery, descends upon the posterior aspect of the maxilla, and sends branches through the alveolar canals of the maxilla for the supply of the upper molar and præmolar teeth (Fig. 63). Some small twigs go to the gum, and others supply the lining membrane of the maxillary sinus.

Plexus Pterygoideus et Vena Maxillaris Interna.—The veins of the infratemporal region are very numerous, but they cannot be studied satisfactorily in an ordinary dissection. They constitute a dense plexus, termed the *pterygoid plexus*, around the external pterygoid muscle. Tributaries corresponding to the branches of the internal maxillary artery open into the network, whilst the blood is led away from its posterior part by a short wide trunk, called the *internal maxillary vein*.[1] That vessel accompanies the first part of the internal maxillary artery into the parotid gland, where it joins the posterior facial vein behind the neck of the mandible.

The pterygoid venous plexus is connected with the cavernous sinus by an emissary vein. It communicates with the inferior ophthalmic vein, through the inferior orbital fissure, and with the anterior facial vein by an anastomosing channel, called the *deep facial vein*, which descends across the external surface of the buccinator muscle.

Articulatio Mandibularis.—Before the external pterygoid muscle is thrown forwards, the mandibular joint must be examined. It is a diarthrodial joint of the ginglymus type, and its cavity is separated into an upper and a lower part by an articular disc. In connection with it there are the following ligaments:—

[1] The internal maxillary vein may be replaced by two venæ comites.

Ligaments Proper.	Accessory Ligaments.
1. Capsula articularis. Lig. temporo-mandibulare.	2. Lig. spheno-mandibulare. 3. Lig. stylo-mandibulare.
Discus Articularis.	

The *articular capsule* encloses the joint cavity. Above, it is attached posteriorly, laterally and medially to the margin of the mandibular fossa, and, anteriorly, to the anterior margin of the articular tubercle. Below, it is attached to the neck of

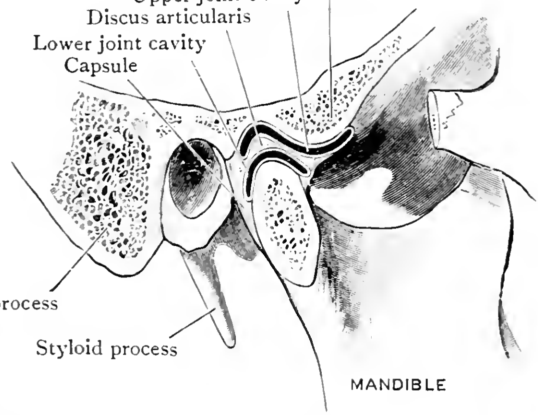

Fig. 64.—Section through the Mandibular Joint.

the mandible; and between its upper and lower attachments it is connected with the margins of the articular disc.

The *temporo-mandibular ligament* is a strong triangular band of the capsule attached, by its base, to the lateral surface of the posterior part of the zygoma and to the tubercle at the root of the zygoma. Its fibres run downwards and backwards to the lateral margin of the neck of the mandible.

The *spheno-mandibular ligament* (O.T. *internal lateral*) is a long membranous band which extends from the spine of the sphenoid to the lingula of the mandible and to the sharp medial margin of the mandibular foramen. It is not in direct relationship with the joint. Above, it lies medial to the external pterygoid muscle and the auriculo-temporal nerve; lower down, the internal maxillary vessels intervene between

it and the neck of the mandible; whilst, still lower, the inferior alveolar vessels and nerve are interposed between it and the ramus of the mandible.

The *stylo-mandibular ligament* is a fibrous band, derived from that portion of the deep cervical fascia which forms a part of the capsule of the parotid gland. It is attached, above, to the styloid process, and, below, to the angle and posterior border of the ramus of the mandible, between the internal pterygoid and masseter muscles.

An examination of the spheno-mandibular and stylo-mandibular ligaments will show that very little is added to the strength of the joint by their presence. The security of the joint depends not so much upon its ligaments as upon the strong muscles of mastication, which keep the head of the mandible in its place.

Fig. 65.—Diagram of the different positions occupied by the head of the mandible and the discus articularis as the mouth is opened and closed.

The *articular disc* is an oval plate of fibro-cartilage, with its long axis directed transversely. It is interposed between the condyle of the mandible below and the mandibular fossa (O.T. glenoid) and the articular tubercle (O.T. eminentia articularis) above, and it divides the joint cavity into an upper and a lower part, each of which is provided with a separate synovial lining. To expose the disc, the temporo-mandibular ligament must be removed. The disc will then be seen to be adapted to the two bony surfaces between which it lies. Above, it is concavo-convex in correspondence with the tuberculum articulare and the mandibular fossa of the temporal bone; whilst below, it is concave, and fits upon the upper aspect of the condyle of the mandible. In the centre it is thin, and in some cases it is perforated. Its circumference is thick, more especially posteriorly. It should be noted also that the external pterygoid muscle is partly inserted into the capsule at its anterior border.

The *synovial stratum* which lines the capsule enclosing the

upper cavity of the joint is of greater extent and looser than that of the lower compartment. The greater extent of the synovial stratum of the upper cavity of the joint is associated with the larger size of the articular surface of the temporal bone as contrasted with the condylar surface.

Movements. — The movements which the mandible can perform at the mandibular joint are the following:—(1) depression; (2) elevation; (3) protraction; (4) retraction; (5) side to side or chewing movements. When the mandible is depressed the articular disc and the condyle move forwards in the mandibular fossa, and the condyle finally takes up a position on the tuberculum articulare. The forward gliding of the disc and condyle in the upper compartment of the joint is accompanied by another movement in the lower compartment of the joint, which consists in a rotation of the condyle of the mandible on the lower surface of the articular disc. Elevation of the mandible or closure of the mouth is brought about by a reverse series of changes in both compartments of the joint. There is some doubt about the position of the transverse axis around which the movements of elevation and depression take place, but it is generally supposed to be situated at the level of the mandibular foramina. Those are the points, therefore, of least movement, and consequently in opening and shutting the mouth the inferior alveolar vessels and nerves are not unduly stretched. In protraction and retraction the movement is confined chiefly to the upper compartment of the joint, and the condyle of the mandible, with the articular disc, glides forwards and backwards upon the temporal articular surface. In the side to side movements of the jaw the mandible is carried alternately from one to the other side, as in the process of chewing.

The muscles on each side which are chiefly engaged in producing these movements are the following:—(1) *depressors*—the platysma, the mylohyoid, and the anterior belly of the digastric; (2) *elevators*—the masseter, internal pterygoid, temporal; (3) *protractors*—the external pterygoid, and to some extent the internal pterygoid and the superficial fibres of the masseter; (4) *retractor*—the posterior fibres of the temporal and the deep fibres of masseter; (5) *side to side movement* is produced by the muscles of opposite sides acting alternately.

Dissection.—The condyle of the mandible must now be disarticulated and thrown forwards with the attached external pterygoid muscle. It is well to detach the articular disc with the head of the bone, in order that it may be more thoroughly examined. Care must be taken not to injure the auriculo-temporal nerve, which lies in close proximity to the medial aspect of the joint. When the disarticulation is complete, draw the muscle forwards by gently pushing the condyle under the internal maxillary artery.

When the external pterygoid has been reflected and the areolar tissue medial to it has been cleaned away the following structures will be exposed. The *middle meningeal artery*; the *mandibular division of the trigeminal nerve* and its branches; the *chorda tympani* branch of the facial nerve, and, in a well-injected subject, the *tympanic* and *accessory meningeal branches of the internal maxillary artery* may be seen. Follow the middle meningeal artery upwards. Just before it enters the foramen spinosum it passes between the two heads of origin by

which the auriculo-temporal nerve springs from the back of the posterior division of the mandibular nerve. Follow the auriculo-temporal nerve backwards and note how close it lies to the medial face of the capsule of the temporo-mandibular joint, before it enters the parotid region and ascends behind the condyle of the mandible to the temporal region. Next clean the upper part of the inferior alveolar nerve. Then turn to the lingual nerve; first clean its surface, then pull it forwards and secure the chorda tympani which joins its posterior border, after passing medial to the inferior alveolar nerve. Note that the mandibular nerve divides into anterior and posterior parts. The posterior division gives off the two roots of the auriculo-temporal nerve and then divides into the inferior alveolar and lingual branches, whilst the anterior division supplies all the muscles of mastication, except the internal pterygoid and sends the sensory buccinator nerve to the mucous membrane and skin over the buccinator muscle. Now secure the *nerve to the internal pterygoid muscle* which springs from the anterior part of the trunk of the mandibular nerve, and, if possible, the small *nervus spinosus* which passes backwards and laterally to the foramen spinosum.

Arteriæ Meningea Media et Tympanica et Ramus Meningeus Accessorius.—The *middle meningeal artery* has already been seen arising from the first part of the internal maxillary artery. It passes upwards, medial to the external pterygoid muscle and lateral to the tensor veli palatini, and disappears from view through the foramen spinosum, by which it enters the cranial cavity (p. 118). It is usually embraced by the two roots of the auriculo-temporal nerve.

The *accessory meningeal artery* and the *tympanic artery* generally arise from the middle meningeal. The *accessory meningeal* inclines forwards and upwards, and enters the cranial cavity by passing through the foramen ovale; the *tympanic* runs upwards and backwards, and reaches the tympanum by passing through the petro-tympanic fissure (O.T. Glaserian). In the tympanic cavity it anastomoses with the stylo-mastoid branch of the posterior auricular artery.

Nervus Mandibularis.—The mandibular branch of the trigeminal nerve arises, within the cranium, from the semilunar (O.T. Gasserian) ganglion, and enters the infratemporal region through the foramen ovale. It is composed of *sensory fibres*, but it is accompanied through the foramen by the small *motor root* of the trigeminal nerve; and by the union of the sensory and motor parts, immediately after they gain the exterior of the cranium, a *mixed nerve-trunk* results, which lies medial to the external pterygoid muscle and lateral to the tensor veli palatini.

Immediately after its exit from the skull the mandibular

nerve gives off the nervus spinosus and the nerve to the internal pterygoid muscle, and, at a slightly lower level, it divides into an anterior division, and a posterior division which almost immediately breaks up into its lingual, alveolar and auriculo-temporal divisions.

The *nervus spinosus* is a very slender twig which enters the cranium by accompanying the middle meningeal artery

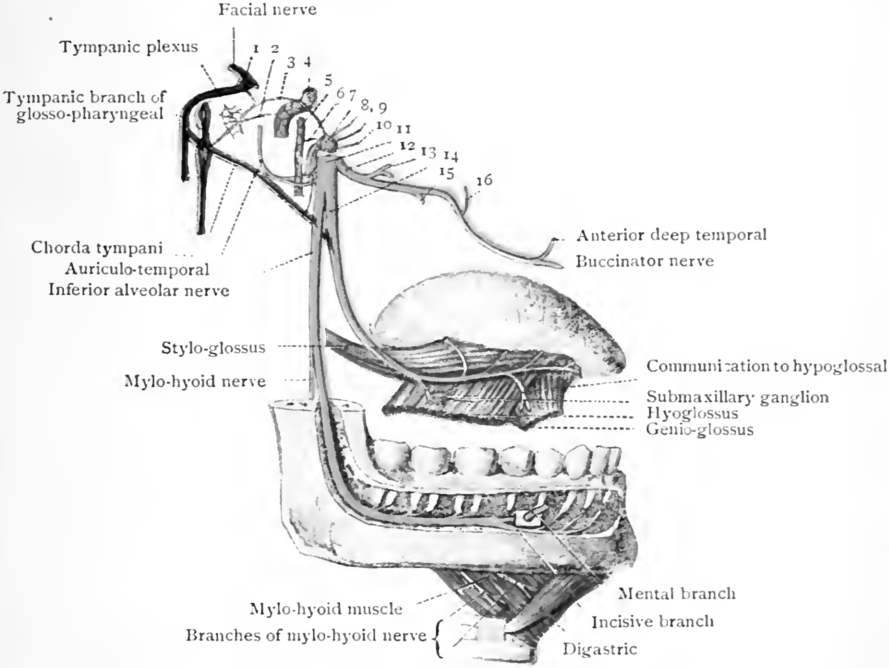

FIG. 66.—Diagram of Mandibular Nerve. (By Prof. A. M. Paterson.) The tongue has been separated from its attachments and raised above the level of the body of the mandible.

16. Pterygoid branch

through the foramen spinosum. It supplies the dura mater, and sends a twig into the tympanum.

The *nerve to the internal pterygoid* will be found, passing forwards, under cover of the posterior border of the upper end of the internal pterygoid muscle. In close relation to its commencement is the *otic ganglion.*

The anterior division arises from the trunk of the mandibular nerve about 5 mm. below the foramen ovale. It consists almost entirely of motor fibres derived from the

motor root of the mandibular nerve; but it contains also a few sensory fibres which are afterwards distributed by its buccinator branch.

It passes downwards and forwards on the medial side of the external pterygoid muscle, and it gives off the following branches:—

1. Masseteric.
2. Two deep temporal.
3. External pterygoid.
4. Buccinator.

Nervus Massetericus.—The masseteric nerve runs horizontally above the external pterygoid muscle, and, after passing through the incisura mandibulæ (O.T. sigmoid notch), posterior to the temporal muscle, it enters the posterior and upper part of the deep surface of the masseter. Before reaching the masseter it gives one or two twigs to the mandibular joint.

Nervi Temporales Profundi.—There are usually two deep temporal nerves, *anterior* and *posterior.* The posterior nerve is the smaller of the two; it frequently arises by a common root with the masseteric. Both deep temporal nerves pass laterally above the external pterygoid, and then turn upwards on the medial wall of the temporal fossa. They supply the temporal muscle.

Nervus Buccinatorius.—The buccinator nerve (O.T. long buccal) is the largest of the branches arising from the anterior division. It proceeds laterally between the two heads of the external pterygoid muscle, and then runs downwards and forwards under cover of the temporal muscle, and under cover of the anterior border of the masseter also, to reach the outer surface of the buccinator muscle. There it unites with branches of the facial nerve to form the *buccal plexus*, from which branches are distributed to the mucous membrane and skin of the cheek.

The buccinator nerve is a sensory nerve, and all the sensory fibres in the anterior division enter into its composition. A few motor fibres, however, are also prolonged into it; they leave it in two branches, viz., (1) in the *nerve to the external pterygoid*, which, as a rule, arises in common with the buccinator nerve; and (2) in the anterior deep temporal nerve to the temporal muscle. The anterior deep temporal nerve springs from the buccinator nerve, either before or after it has reached the lateral surface of the external pterygoid, and proceeds upwards to supply the anterior part of the temporal

muscle (Fig. 63). In some cases the buccinator nerve pierces the temporal muscle instead of passing under cover of it.

The posterior division of the mandibular nerve consists mainly of sensory fibres, but it still contains a few motor fibres which ultimately pass into its alveolar branch and thence to the mylo-hyoid nerve.

Nervus Auriculo - Temporalis.—The auriculo - temporal nerve springs by two roots from the posterior division of the mandibular nerve, under cover of the external pterygoid. The two roots are composed of sensory fibres and each receives a communication from the otic ganglion, by means of which it is brought, indirectly, into association with the glosso-pharyngeal nerve. The roots embrace the middle meningeal artery, and unite posterior to it to form a stem which runs backwards between the neck of the mandible and the spheno-mandibular ligament. At the interval between the ear and mandible it turns upwards, in relation to the antero-medial surface of the parotid gland, crosses the zygoma in company with the superficial temporal artery, and enters the scalp, where it breaks up into terminal branches (Fig. 51).

Its branches are: (1) one or two strong branches of communication to the upper division of the facial nerve; (2) a few slender filaments which enter the posterior aspect of the mandibular joint; (3) some twigs to the parotid gland; (4) terminal filaments to the skin over the temporal region and summit of the head; (5) auricular branches.

The *auricular* branches are usually *two* to the skin lining the upper part of the interior of the external meatus, and *two* to the integument over the upper and anterior part of the auricle. The former gain the interior of the meatus by passing between the osseous and cartilaginous portions of the canal.

Nervus Alveolaris Inferior.—The inferior alveolar nerve (O.T. inferior dental) is the largest branch of the posterior division of the mandibular nerve. It emerges from under cover of the external pterygoid, at the lower border of the muscle, passes downwards along the lateral surface of the spheno-mandibular ligament, and enters the mandibular foramen. The inferior alveolar artery runs downwards posterior to it, whilst the lingual nerve is anterior to it and upon a somewhat deeper plane. The inferior alveolar is a sensory nerve, but a few fibres from the motor root are prolonged downwards within its sheath as far as the mandibular foramen.

At that point they separate off as the slender mylo-hyoid nerve (Figs. 63, 68).

The *mylo-hyoid nerve*, accompanied by the artery of the same name, pierces the spheno-mandibular ligament and proceeds downwards and forwards, in a groove upon the medial surface of the mandible, to the digastric triangle. A narrow prolongation of the spheno-mandibular ligament bridges over the groove and holds the nerve and vessel in position. In the digastric triangle the mylo-hyoid nerve has been dissected already (p. 129). It breaks up into numerous branches for the supply of two muscles, viz., (1) the mylo-hyoid, and (2) the anterior belly of the digastric (Fig. 68).

Nervus Lingualis.—The lingual nerve is entirely sensory. In the first part of its course, like the other branches of the mandibular nerve, it lies medial to the external pterygoid muscle. As it descends it appears at the lower border of the muscle. Then it proceeds downwards and anteriorly, between the internal pterygoid muscle and the mandible, and enters the submaxillary region, where it will afterwards be traced to the tongue. It lies anterior to and on a slightly deeper plane than the inferior alveolar nerve. It gives off no branches in the infratemporal region, but, whilst still under cover of the external pterygoid, it is joined at an acute angle by the *chorda tympani branch* of the facial nerve. Not infrequently, also, a communicating twig passes between it and the inferior alveolar nerve.

Chorda Tympani.—The chorda tympani is a slender nerve which arises from the facial in the canalis nervi facialis (O.T. aqueduct of Fallopius). It gains the infratemporal region by traversing the tympanic cavity and appearing through the medial part of the petro-tympanic fissure (O.T. Glaserian), whence it runs downwards and forwards, medial to the spheno-mandibular ligament. It is joined by a slender filament from the otic ganglion, and it unites with the lingual nerve a short distance below the upper end of the latter.

Dissection.—The student should now endeavour, by means of a Hey's saw, a chisel, and the bone forceps, to remove the outer table of the mandible, and thus open up the mandibular canal.

Structures within the Mandibular Canal.—The mandibular canal is traversed by the *inferior alveolar vessels and nerve*, which give off twigs to the roots of the molar and præmolar

teeth. Both the artery and the nerve terminate by dividing into a mental and an incisor branch.

The *mental artery and nerve* appear on the face through the mental foramen, and have been examined already; the *incisor artery and nerve* pass forwards to the symphysis and send up twigs to the canine and incisor teeth. The vessel anastomoses, in the bone, with the corresponding artery of the opposite side.

SUBMAXILLARY REGION.

The superficial area of the submaxillary region has been dissected already, under the name of the submental triangle of the digastric triangle (p. 127). It is now necessary to carry the dissection to a deeper plane, in order to expose a number of parts in connection with the tongue and floor of the mouth. The structures to be displayed are:—

1. Submaxillary gland and its duct.
2. Sublingual gland.
3. Side of the tongue, and the mucous membrane of the mouth.
4. Muscles.
   - Mylo-hyoid.
   - Digastric.
   - Stylo-hyoid.
   - Hyoglossus.
   - Stylo-glossus.
   - Genio-hyoid.
   - Genio-glossus.
5. Nerves.
   - Mylo-hyoid.
   - Hypoglossal.
   - Lingual.
   - Glosso-pharyngeal.
6. Submaxillary ganglion.
7. Lingual artery and veins.
8. Part of the external maxillary artery.
9. Stylo-hyoid ligament.

***Dissection.*—To prepare the part for dissection, it is necessary to throw back the head to its full extent, and turn it slightly to the opposite side. If the stuffing in the mouth has not been previously removed, it should be taken out now. When that has been done, divide the external maxillary artery and the anterior facial vein at the point where they cross the lower border of the mandible. Next, detach the anterior belly of the digastric from its attachment to the anterior part of the medial aspect of the lower border of the mandible; and then, with the saw, cut through the mandible lateral to the median plane.[1]**

[1] If the part is soft and pliable there may be no necessity to make this division of the bone.

It is essential that the division of the anterior part of the mandible should be slightly lateral to the median plane on each side, in order that the median part of the bone, with the attachments of the genioid muscles, may be left intact.

After the division of the bone has been completed the lower border of the lateral part of the mandible must be everted,

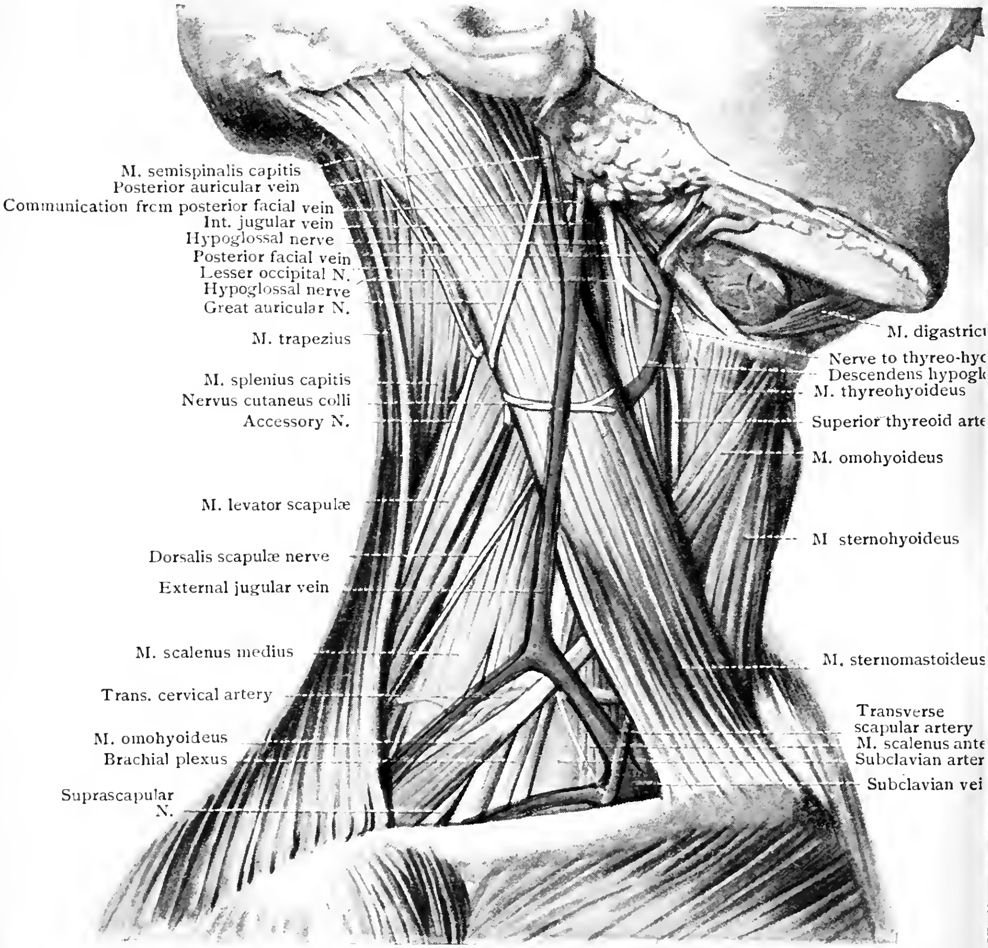

FIG. 67.—The Triangles of the Neck seen from the side. The clavicular head of the sterno-mastoid muscle was small, and therefore a considerable part of the scalenus anterior muscle is seen.

turned slightly upwards, and fixed in position with hooks. When that has been done the boundaries and contents of the submaxillary region can be examined.

Part of the region has already been seen as the digastric portion of the anterior triangle of the neck, but it will now be obvious that the region occupied by the submaxillary gland is much more extensive than the digastric triangle ; for, although

both are bounded anteriorly and posteriorly by the anterior and posterior bellies of the digastric muscle, the upper boundary of the digastric triangle is the lower border of the mandible, whilst the submaxillary region extends upwards to the level of the mylo-hyoid ridge on the inner surface of the mandible.

After the mandible has been turned upwards the dissector should proceed, in the first place, to examine the relations of the digastric and stylo-hyoid muscles, then the mylo-hyoid muscle, and afterwards he must study the submaxillary and sublingual glands and the deeper structures which are found in the medial boundary of the submaxillary region.

Musculus Digastricus.—The digastric muscle limits the submaxillary region inferiorly, and separates it from the carotid and submental triangles (Figs. 67, 68).

The *anterior belly* of the digastric springs from the inner part of the lower border of the mandible, close to the symphysis; the *posterior belly* arises from the mastoid notch of the temporal bone, on the medial side of the mastoid process. The two bellies converge upon the upper border of the hyoid bone, where they are united by an intermediate tendon, which is attached to the hyoid bone, at the junction of the body with the greater cornu, by a strong loop of fibrous tissue developed from the deep cervical fascia. Posterior to the loop, through which it plays, the intermediate tendon passes through the cleft lower end of the stylo-hyoid muscle.

Relations.—The anterior belly is covered by the skin, superficial fascia and the platysma, and the deep fascia. It is overlapped by the anterior border of the submaxillary gland, and its deep surface is in contact with the mylo-hyoid muscle. Its anterior border is the posterior boundary of the submental triangle, and its posterior border is the anterior boundary of the digastric triangle.

The relations of the posterior belly are more numerous and important. Posteriorly, it is covered by the mastoid process and the attachments of the sterno-mastoid and splenius capitis muscles. Between the mastoid process and the angle of the mandible it forms part of the postero-medial boundary of the parotid space and is covered by the parotid gland; next, it is covered by the angle of the mandible and the insertion of the internal pterygoid muscle. As it lies in the anterior triangle it is covered by the skin, the superficial fascia and platysma, and the deep fascia; it is crossed by the anterior facial vein, and is overlapped by the posterior part of the submaxillary gland.

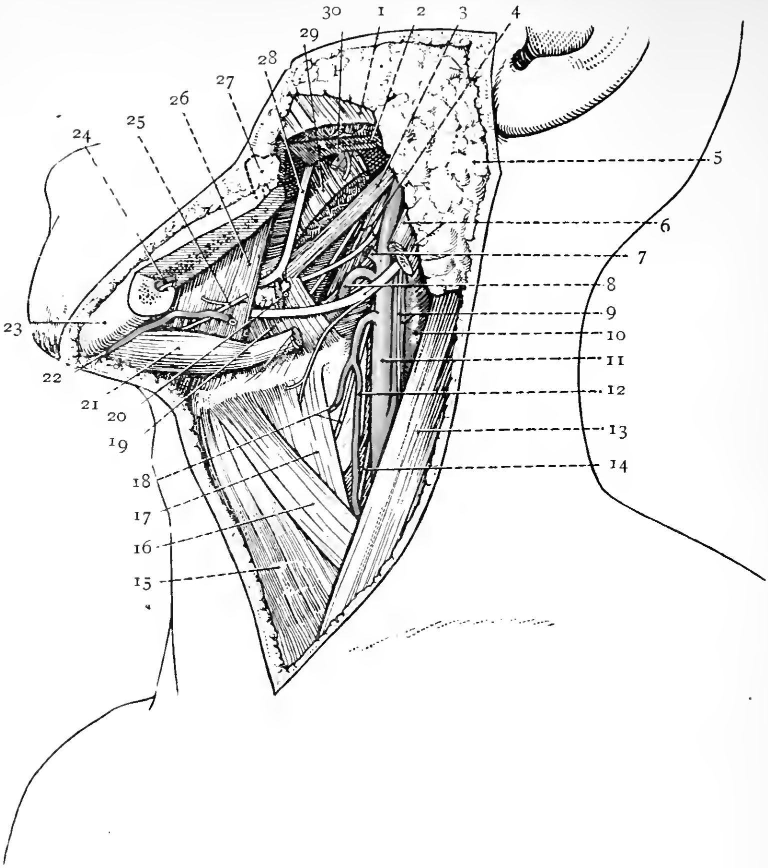

FIG. 68.—Deep dissection of the Infratemporal and Submaxillary Regions.

15. Sterno-hyoid muscle.
16. Omo-hyoid muscle.
17. Thyreo-hyoid muscle.
18. Laryngeal branch of superior thyreoid artery and internal laryngeal nerve.
19. Hyoglossus muscle.
20. Deep part of submaxillary gland and duct of gland.
21. Anterior belly of digastric muscle.
22. Submental branch of external maxillary artery.
23. Mandible.
24. Inferior alveolar artery and nerve.
25. Mylo-hyoid nerve.
26. Mylo-hyoid muscle.
27. Position of last molar tooth of mandible.
28. Lingual nerve.
29. Internal pterygoid muscle.
30. Inferior alveolar nerve, and mylo-hyoid branch with inferior alveolar artery.

It is superficial to the internal jugular vein, the internal and the external carotid arteries, the external maxillary artery,

the middle constrictor of the pharynx, and the lower and posterior part of the hyoglossus muscle. The accessory nerve passes backwards and downwards between it and the internal jugular vein, and the occipital artery passes upwards and backwards under cover of its lower border, superficial to the accessory nerve. The hypoglossal nerve descends vertically on its deep surface in the angle between the internal jugular vein and the internal carotid artery, and the glosso-pharyngeal nerve passes forwards and downwards between it and the internal carotid. The posterior auricular artery runs upwards and backwards along the posterior part of its upper border under cover of the postero-medial surface of the parotid, and the stylo-hyoid muscle descends along the same border (Fig. 68).

The posterior belly is supplied by the *facial nerve*, and the anterior belly is supplied by the *mylo-hyoid branch* of the inferior alveolar nerve.

If the digastric acts from its posterior attachment it depresses the mandible. If the mandible is fixed and the diagastric acts from its anterior attachment it helps to pull the head backwards. If both the bellies act simultaneously the hyoid bone is raised.

Musculus Stylohyoideus.—The stylo-hyoid muscle is a small muscular bundle which springs from the posterior border and lateral surface of the middle third of the styloid process and descends along the upper border of the posterior belly of the digastric. It divides below into two slips which embrace the intermediate tendon of the digastric and are then inserted into the hyoid bone, at the junction of the greater cornu with the body. Its main relations are practically the same as those of the posterior belly of the digastric, but it is not under cover of the mastoid process, the sterno-mastoid, and the splenius muscles. It is supplied by the *facial nerve.* It raises the hyoid bone and draws it backwards.

Dissection.—Turn the anterior part of the submaxillary gland backwards, and clean the posterior part of the mylo-hyoid muscle, which lies deep to it. Note that a process, the *deep part* of the gland, springs from the medial surface of the superficial part and passes forwards, deep to the mylo-hyoid. Dissect the external maxillary artery out of the deep sulcus in the posterior part of the gland, without injuring its submental branch, which runs forwards, along the lower border of the mandible; then

displace the posterior part of the gland forwards and expose the hypoglossal nerve immediately above the greater cornu of the hyoid bone, and, at a higher level, the lingual nerve. Both nerves lie on the lateral surface of the hyoglossus muscle. Hanging from the lower border of the lingual nerve is the small submaxillary ganglion, from which several branches pass to the gland. Note again the deep part of the gland, springing from the medial surface of the superficial part, and also the duct of the gland emerging from the superficial part of the gland and passing forwards, with the deep part, between the mylo-hyoid muscle laterally and the hyoglossus medially. Then study the position and relations of the superficial portion of the gland. The relations of the deep part will be seen after the mylo-hyoid is reflected.

Glandula Submaxillaris.—The submaxillary salivary gland consists of a superficial larger portion and a deep smaller portion. The superficial portion is lodged in a space which is bounded anteriorly by the anterior belly of the digastric; posteriorly by the posterior belly of the digastric, the stylo-hyoid, and the stylo-mandibular ligament; below by the deep fascia of the neck; laterally by the medial surface of the body of the mandible and the lower part of the medial surface of the internal pterygoid muscle; and medially by the mylo-hyoid and hyoglossus muscles. The fascial relations of the gland have been described already (p. 123). The dissector should note now that, in accordance with the contour of the space in which it lies, he can recognise that the superficial part of the gland possesses an anterior and a posterior extremity, and three more or less well-defined surfaces, inferior, lateral, and medial. The *posterior extremity* abuts against the stylo-mandibular ligament, which separates it from the parotid, and it overlaps the stylo-hyoid and posterior belly of the digastric. It is cleft by a groove in which lies the external maxillary artery. The *anterior extremity* rests on the anterior belly of the digastric muscle.

The *inferior surface* is covered by the layer of deep cervical fascia which extends upwards from the greater cornu of the hyoid bone to the lower border of the mandible; it is crossed posteriorly, under cover of the deep fascia, by the anterior facial vein. Along its upper border lie the majority of the submaxillary lymph glands; the external maxillary artery turns round between it and the lower border of the mandible, at the anterior border of the masseter; and the submental branch of the external maxillary artery runs forwards in the angle between it and the mandible.

The *lateral surface* is in relation, posteriorly, with the lower part of the medial surface of the internal pterygoid, and anteriorly with the medial surface of the body of the mandible, below the mylo-hyoid ridge. The external maxillary artery, as it lies in the groove in the posterior end of the gland, and before it turns round the lower border of the mandible, runs forwards and downwards between this surface

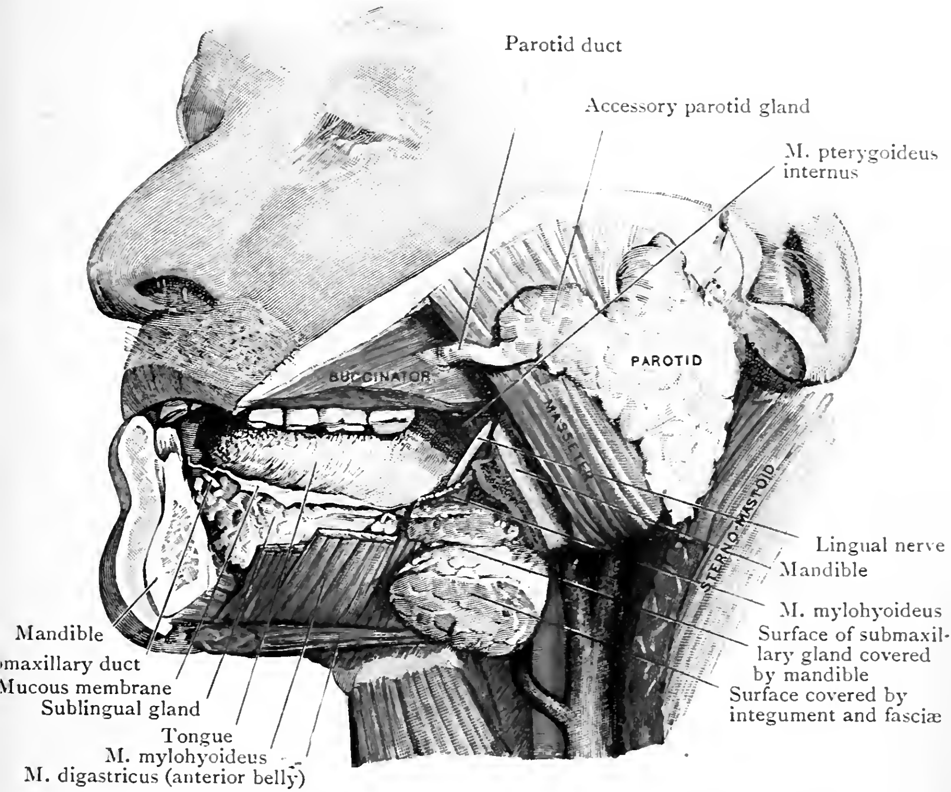

FIG. 69.—Dissection of the Parotid, Submaxillary, and Sublingual Glands.

and the internal pterygoid; and the mylo-hyoid artery and nerve lie between it and the body of the mandible before they pass, more anteriorly, to the medial surface of the gland. The *medial surface* is in relation with the mylo-hyoid and hyoglossus, the lingual nerve and the submaxillary ganglion, and the hypoglossal nerve. It overlaps the stylo-hyoid muscle, both bellies of the digastric, and, sometimes, the greater cornu of the hyoid bone. The deep part of the gland and the duct both spring from the medial surface

before they pass forwards between the mylo-hyoid and the hyoglossus muscles (Fig. 71).

The nerve supply of the gland is derived from the lingual nerve, the submaxillary ganglion, and the sympathetic plexus on the external maxillary artery; its vascular supply consists of small glandular branches from the external maxillary artery.

The relations of the deep part of the gland and the duct will be investigated after the mylo-hyoid has been reflected.

> ***Dissection.***—Displace the superficial part of the gland and the submental branch of the external maxillary artery backwards; cut the mylo-hyoid vessels and nerve, and turn the anterior belly of the digastric downwards; then clean the mylo-hyoid muscle and examine its attachments.

Musculus Mylohyoideus.—The mylo-hyoid muscle is a thin sheet of muscular fibres, which arises from the mylo-hyoid line upon the medial surface of the body of the mandible, by an origin which extends from the last molar tooth to the symphysis. Its fibres are directed downwards, medially and forwards, and present two different modes of insertion. The posterior fibres are inserted into the body of the hyoid bone; they, however, form a comparatively small part of the muscle. Most of the fibres are inserted into a median raphe which extends between the symphysis of the mandible and the body of the hyoid bone. The two mylo-hyoid muscles, therefore, stretch across from one side of the body of the mandible to the other, in front of the hyoid bone, and constitute a floor for the anterior part of the mouth which is frequently termed the *diaphragma oris.* The mylo-hyoid muscle is supplied by the *mylo-hyoid branch* of the *inferior alveolar nerve.* It elevates the hyoid bone, the tongue and the floor of the mouth in the movement of swallowing.

> ***Dissection.***—Cut the mylo-hyoid muscle a little below its origin from the mylo-hyoid ridge and turn it downwards and forwards. Be careful not to injure the mucous membrane of the mouth, which lies in contact with the upper surface of the muscle near its origin.

Parts exposed by the Reflection of the Mylo-hyoid (Fig. 70).—Part of the tongue, and a number of structures associated with it are now brought into view. First, note the mucous membrane stretching from the tongue to the

inner side of the mandible ; then, identify the various muscles. The *hyoglossus*, a portion of which was previously visible behind the mylo-hyoid, is fully exposed. It is a quadrangular sheet of fleshy fibres which extends from the hyoid bone to the side of the tongue. Mark its position, because all the structures in the region now under consideration have a more or less intimate relationship to it. Thus, posterior and also superficial to its upper part, the *stylo-glossus muscle* will be recognised, whilst anterior to it are the *genio-glossus* and the

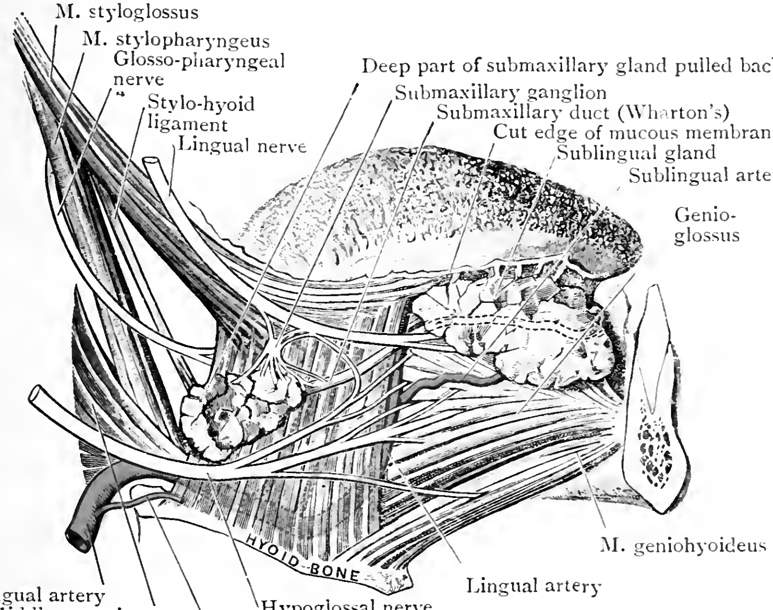

FIG. 70.—Dissection of Submaxillary Region.

genio-hyoid. The genio-hyoid muscle occupies the antero-inferior part of the region, whilst the anterior part of the genio-glossus is seen in the interval between the genio-hyoid and the hyoglossus. Upon the surface of the hyoglossus, the lingual and hypoglossal nerves, the connecting loop between them, the deep portion of the submaxillary gland, with the submaxillary duct, and the submaxillary ganglion, are to be dissected. The *lingual nerve* occupies the highest level, and passes forwards upon the muscle, near its insertion into the tongue. The *hypoglossal nerve*, with its *vena comitans* and the lingual vein, crosses the muscle close to the hyoid bone,

whilst the *deep part of the submaxillary gland* and the *submaxillary duct* (Wharton's) occupy an intermediate place. Although the *submaxillary ganglion* is very small, its relations are so precise that it is very easily found. By seizing the lingual nerve and dissecting carefully in the interval between it and the deep part of the submaxillary gland, the dissector will expose the ganglion, and its roots and branches of distribution (Fig. 70). Upon the genio-glossus, anterior to the

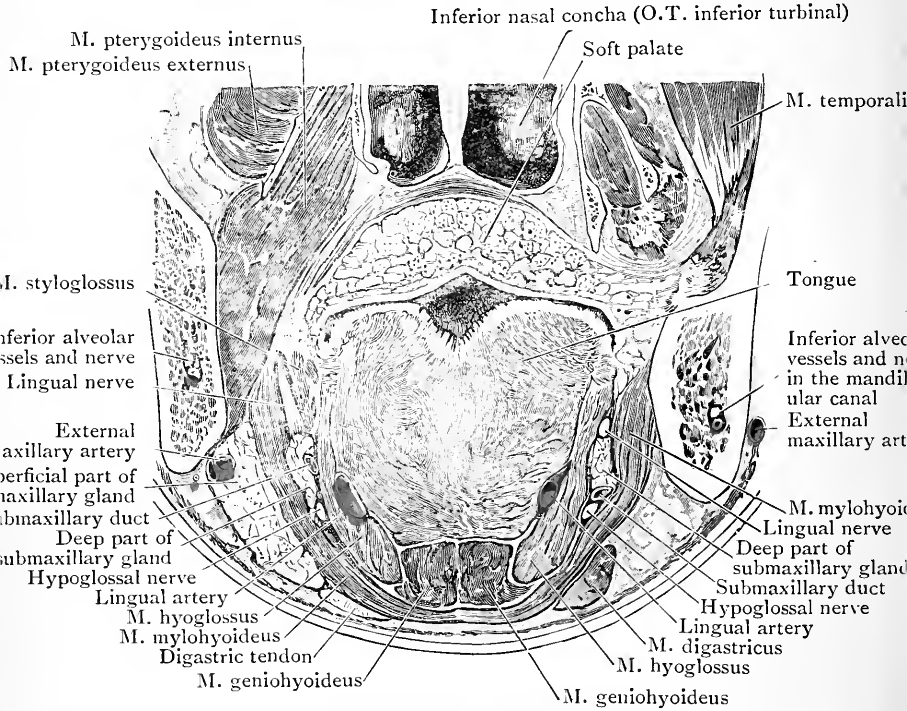

FIG. 71.—Frontal section through the Tongue and Submaxillary Region in a plane posterior to the molar teeth.

hyoglossus, the *sublingual gland*, with its artery of supply will be seen. If the stylo-hyoid and the posterior belly of the digastric are displaced backwards, certain structures will be seen passing under cover of the posterior margin of the hyoglossus muscle. They are :—(1) the glosso-pharyngeal nerve, immediately below the stylo-glossus muscle; (2) the stylo-hyoid ligament, a little lower down; and (3) the lingual artery, close to the hyoid bone (Fig. 68).

Musculus Hyoglossus.—The hyoglossus is a quadrate, flat muscle which arises from the whole length of the greater cornu,

and also from the body of the hyoid bone. Its fibres pass upwards to the posterior part of the side of the tongue, medial to the stylo-glossus. The hyoglossus is supplied by the *hypoglossal nerve.* It helps to depress the tongue and to pull its anterior part backwards.

Musculus Stylo-glossus.—The stylo-glossus muscle is an elongated fleshy slip which takes origin from the anterior aspect of the styloid process, near its tip, and, to a slight extent, from the upper part of the stylo-hyoid ligament also. It passes down-

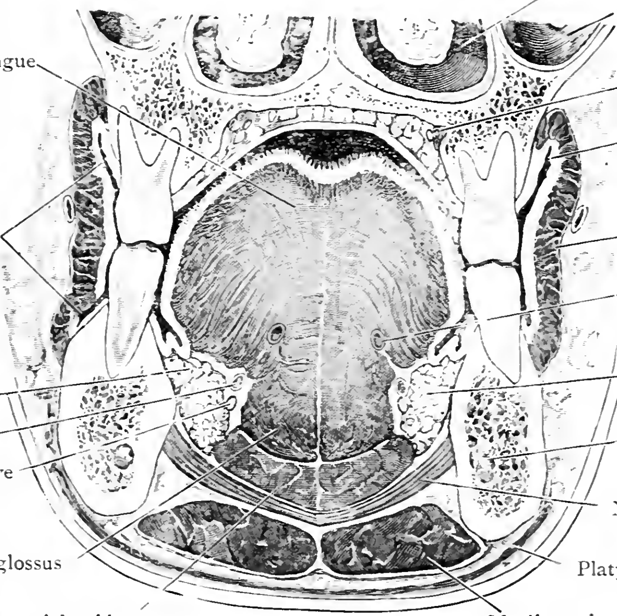

FIG. 72.—Frontal section through the Closed Mouth in the plane of the second molar teeth.

wards and forwards, and its fibres may be traced upon the side of the tongue as far as the tip. Some of them decussate with the fasciculi of the hyoglossus muscle. It pulls the tongue backwards, and its nerve of supply is derived from the *hypoglossal nerve.*

Musculus Geniohyoideus. — The genio-hyoid muscle is placed close to the median plane, in contact with its fellow of the opposite side. It is a short muscle which arises from the lower mental spine upon the posterior surface of the symphysis of the mandible, and extends downwards and backwards to

gain insertion into the anterior aspect of the body of the hyoid bone. It is supplied by the *hypoglossal nerve*. It pulls the hyoid bone upwards and forwards.

The Deep Part of the Submaxillary Gland.—It has been noted already that the small, deep part of the submaxillary gland springs from the medial surface of the superficial part, at the posterior border of the mylo-hyoid muscle. It will now be obvious that it passes forwards and upwards, between the mylo-hyoid laterally and the hyo-glossus and genio-glossus medially, until it comes into contact with the sublingual gland. It is accompanied by the lingual nerve and the submaxillary duct, both of which lie on its medial surface (Fig. 72).

Ductus Submaxillaris.—The duct of the submaxillary gland (O.T. Wharton's duct) emerges from the medial surface of the main part of the gland, and proceeds, with the deep part of the gland, forwards and upwards upon the hyo-glossus muscle. At first it lies between the lingual nerve above and the hypoglossal nerve below. Reaching the surface of the genio-glossus muscle, it is crossed laterally, and then below and medially, by the lingual nerve. Then it passes to the medial side of the sublingual gland, and gains the floor of the mouth, where it opens by a small orifice placed on the summit of a papilla which lies close to the side of the frenulum linguæ.

The wall of the duct is much thinner than that of the parotid duct. If a small opening is made in it, the dissector will experience little difficulty in passing a fine probe or bristle along it into the mouth.

Glandula Sublingualis.—The sublingual gland lies in the floor of the mouth, and is the smallest of the larger salivary glands. It is almond-shaped, about one inch and a half long; and its relations are very definite. Its prominent *upper border* can be seen within the mouth, beneath the anterior part of the tongue, where it is covered by a fold of mucous membrane termed the plica sublingualis (Fig. 105). *Medially*, it rests upon the genio-glossus muscle, whilst, *laterally*, it lies against the medial aspect of the body of the mandible, immediately lateral to the symphysis and above the mylo-hyoid line. *Below*, it is supported by the mylo-hyoid muscle. Its anterior extremity reaches the median plane, above the anterior border of the genio-glossus, and is in contact with its fellow of the opposite side. The duct of

the submaxillary gland and the lingual nerve are prolonged forwards, medial to the sublingual gland.

Numerous small ducts (the number varying from eight to twenty) proceed from the sublingual gland. As a rule, they open into the mouth on the summit of the plica sublingualis (Birmingham).

Nervus Lingualis.—In the dissection of the infratemporal region, the lingual nerve was seen passing downwards between the ramus of the mandible and the internal pterygoid muscle. As it descends, it inclines forwards, and, after passing over the attachment of the superior constrictor muscle of the pharynx to the posterior end of the mylo-hyoid line, it lies below and posterior to the last molar tooth (Fig. 68), between the mucous membrane of the mouth and the body of the mandible. At that point it is in danger of being hurt by the clumsy extraction of one of the lower molars, and there also it may be divided by the surgeon, from the inside of the mouth. In its further course the nerve keeps close to the side of the tongue, crossing the styloglossus and the upper part of the hyoglossus, and, beyond that, the submaxillary duct. Its terminal branches are placed immediately under cover of the mucous membrane of the mouth, and it can be traced as far as the tip of the tongue.

The *branches* which proceed from the lingual nerve in the submaxillary region are of two kinds—(1) twigs of communication; (2) branches of distribution.

Twigs of Communication.	1. Two or more to the submaxillary ganglion. 2. One or two which descend along the anterior border of the hyoglossus muscle to unite with the hypoglossal nerve.
Branches of Distribution.	1. Slender filaments to the mucous membrane of the mouth and gums. 2. A few twigs to the sublingual gland. 3. Branches to the tongue.

The *lingual branches* pierce the substance of the tongue, and then incline upwards to supply the papillated mucous membrane over the anterior two-thirds of the organ.

Ganglion Submaxillare.—The small submaxillary ganglion lies upon the upper part of the hyoglossus muscle, in the interval between the lingual nerve and the deep part of the submaxillary gland. In size, it is not larger than the head of a large pin; and, when freed from the connective tissue surrounding, it will be seen to be suspended from the lingual nerve

by two short branches, which enter its upper border, and are separated by a distinct interval. The posterior connecting twig is frequently replaced by two or three filaments, which form the sensory and secretory roots of the ganglion, whilst the anterior connecting branch must be looked upon as a twig given by the ganglion to the lingual nerve.

Like the other ganglia developed in connection with the branches of the trigeminal nerve, the submaxillary ganglion has three roots—viz., (1) a *sensory root* from the lingual nerve; (2) a *secretory root* from the chorda tympani; and (3) a *sympathetic root* from the plexus around the external maxillary artery.

From its lower border several minute twigs proceed; they are distributed—(1) to the submaxillary gland and duct; (2) to the sublingual gland, from the branch given by the ganglion to the lingual nerve; and (3) to the mucous membrane of the mouth.

Nervus Hypoglossus.—The hypoglossal nerve has been traced, in the dissection of the anterior triangle, to the point where it disappears under cover of the mylo-hyoid muscle (p. 130). It is now seen passing forwards upon the hyoglossus muscle, above the hyoid bone and below the level of the deep part of the submaxillary gland. At the anterior border of the hyoglossus it gains the surface of the genio-glossus muscle, into the substance of which it sinks; and finally it breaks up into branches which supply the muscular substance of the tongue. Upon the hyoglossus muscle it is accompanied by the lingual vein.

The *branches* which spring from the hypoglossal nerve in the region of the floor of the mouth are very numerous, and are distributed entirely to muscles. It supplies—(1) the stylo-glossus; (2) the hyoglossus; (3) the genio-glossus; (4) the genio-hyoid; and (5) the intrinsic muscles of the tongue.

In addition, it communicates freely with the lingual nerve. The more apparent of the connections take the form of one or more loops which lie on the lateral surface of the anterior part of the hyoglossus. Other communications with the lingual nerve are effected in the substance of the tongue.

Dissection.—The hyoglossus should now be carefully detached from the hyoid bone, and thrown upwards towards the tongue, but the structures which lie upon the superficial surface of the muscle need not be divided. By the reflection of the hyoglossus muscle the following structures will be fully displayed, and must be cleaned—(1) the profunda linguæ artery

and the veins which accompany it; (2) the dorsales linguæ arteries and veins; (3) the posterior part of the genio-glossus; (4) the origin of the middle constrictor of the pharynx; and (5) the attachment of the stylo-hyoid ligament.

Musculus Genioglossus.—The genio-glossus is a flat triangular muscle, the medial surface of which is in contact with its fellow of the opposite side, in the median plane. It arises by a short pointed tendon from the upper mental spine on the posterior aspect of the symphysis of the mandible, and, from that point, its fleshy fasciculi spread out in a fan-like manner. By far the greater part of the muscle is inserted into the tongue, by an insertion which extends throughout the whole length of the organ, from the tip to the base; below the tongue, a few fibres reach the side of the pharynx. The genio-glossus is supplied by twigs from the *hypoglossal nerve.* It can project the tip of the tongue forwards and depress the whole organ in the floor of the mouth.

Arteria Lingualis. — As the lingual artery is now fully exposed, it can be conveniently studied at this stage. It springs from the anterior aspect of the external carotid, and is separable into two parts—viz., (1) a part extending from its origin to the posterior border of the hyoglossus muscle; (2) a part lying in relation to the upper border of the hyoid bone, and extending to the anterior border of the hyoglossus, where it divides into two terminal branches, the sublingual and the deep artery of the tongue (Figs. 68, 70).

The *first part* has been fully examined in a previous dissection. It lies in the carotid triangle of the neck, and is therefore comparatively superficial. It is crossed, superficially, by the hypoglossal nerve, and lies, medially, against the middle constrictor. The *second part* passes forwards along the upper border of the greater cornu of the hyoid bone, and is covered by the hyoglossus muscle, which intervenes between it and the hypoglossal nerve. The nerve, however, is placed at a slightly higher level. The deep or medial relations of the artery, in the second stage of its course, are the middle constrictor of the pharynx and the genio-glossus.

The *branches* of the lingual artery are:—

1. Supra-hyoid, from the *first* part (p. 133).
2. Dorsales linguæ, from the *second* part.
3. Sublingual.
4. Profunda.

Rami Dorsales Linguæ.—The dorsales linguæ branches are generally two or more in number. They pass upwards, under cover of the hyoglossus muscle, to end in twigs to the mucous membrane covering the pharyngeal part of the dorsum of the tongue. Some twigs are supplied also to the muscular substance of the organ, and a few may be traced backwards into the palatine tonsil.

Arteria Sublingualis.—The sublingual artery springs from the end of the second part of the lingual artery and emerges from under cover of the anterior border of the hyoglossus; then it ascends, upon the genio-glossus, to the sublingual gland, which it supplies. It gives branches to the surrounding muscles; and it anastomoses with its fellow of the opposite side and, through the mylo-hyoid muscle, with the submental branch of the external maxillary artery.

Arteria Profunda Linguæ.—The deep artery of the tongue ascends almost vertically, upon the genio-glossus, overlapped by the anterior border of the hyoglossus; when it reaches the under surface of the tongue, it runs towards the tip and ends in terminal branches. To expose it divide the mucous membrane along its course; then it will be seen to lie close to the attachment of the frenum of the tongue, and to be continued forwards in the interval between the genio-glossus and the inferior longitudinal muscle. Its course is tortuous, to allow for the protrusion or elongation of the tongue; and it gives off numerous branches.

Venæ Linguales.—The lingual artery may be accompanied by two small venæ comites which lie beside it under cover of the hyoglossus; but the main vein of the tongue crosses the lateral surface of the hyoglossus below the hypoglossal nerve; and another smaller vein, the *vena comitans hypoglossi*, runs backwards above the hypoglossal nerve. At the posterior border of the hyoglossus the lingual vein is joined by the vena comitans hypoglossi and the venæ comites of the artery, if they are present; then it passes backwards to end either in the common facial vein or the internal jugular vein.

Ligamentum Stylohyoideum.—The stylo-hyoid ligament is the last structure to be examined in this dissection. It is a fibrous cord which springs from the tip of the styloid process and passes antero-inferiorly to be attached, under cover of the hyoglossus muscle, to the lesser cornu of the hyoid bone. It is not uncommon to find it partially ossified; in

other cases it may assume a ruddy hue and contain muscular fibres.

OTIC GANGLION AND TENSOR VELI PALATINI.

During the dissection of the submaxillary region the dissector noted a nerve ganglion, *the submaxillary ganglion*, connected with the lingual branch of the mandibular nerve; and, when he was examining the infratemporal region, reference was made to the otic ganglion, which is associated with the trunk of the mandibular nerve and the branch which it supplies to the internal pterygoid muscle. The otic ganglion and its connections should now be displayed, and afterwards the tensor veli palatini muscle should be cleaned and followed from its origin downwards to the hamulus of the medial pterygoid lamina.

Dissection.—Cut the lingual and inferior alveolar nerves immediately below their origins; evert the upper part of the mandibular nerve, and define the otic ganglion; then divide the internal pterygoid, along the posterior border of the lateral pterygoid lamina; depress the lower part of the muscle and clean the tensor veli palatini, which lies medial to the middle meningeal artery, the otic ganglion and the mandibular nerve, and separates them from the lateral surface of the auditory tube.

Ganglion Oticum.—The otic ganglion is a minute, oval body, not easily found. It lies immediately below the foramen ovale, between the mandibular nerve laterally, the tensor veli palatini medially, and the middle meningeal artery posteriorly; it is intimately associated with the origin of the nerve to the internal pterygoid (Fig. 66).

The otic ganglion is usually described as receiving motor, sensory, and sympathetic roots. The *motor root* is supplied by the nerve to the internal pterygoid muscle; the *sympathetic root* comes from the plexus around the middle meningeal artery. In addition to those roots, the *lesser superficial petrosal nerve* enters the posterior border of the ganglion, and conveys *sensory fibres* to it.

The following are the *branches* which proceed from the otic ganglion:—

Branches of distribution.	A twig which passes downwards and forwards to the tensor veli palatini. (O.T. Tensor palati.) A twig which proceeds upwards and backwards to supply the tensor tympani.
Connecting branches.	One or more fine filaments to one or both of the roots of the auriculo-temporal nerve. A minute communicating filament to the chorda tympani.

Musculus Tensor Veli Palatini.—The tensor of the soft palate is a flat, triangular muscle which is closely applied to the deep surface of the internal pterygoid muscle. It arises from the scaphoid fossa at the root of the medial pterygoid lamina, from the posterior border of the lower surface of the great wing of the sphenoid, from the spine of the sphenoid, and from the lateral aspect of the auditory tube (O.T. Eustachian). It descends to the lower end of the medial pterygoid lamina, and ends in a tendon which turns horizontally, under the hamulus, into the soft palate, where its attachments will be seen later when the soft palate is dissected.

THE GREAT VESSELS AND NERVES OF THE NECK.

As soon as the dissection of the infratemporal and the submaxillary regions is completed, the dissector should turn to the study of the external carotid artery and its relations.

Arteria Carotis Externa.—The external carotid artery is one of the two terminal branches of the common carotid. It commences at the level of the upper border of the thyreoid cartilage, opposite the fibro-cartilage between the third and fourth cervical vertebræ; and, after running upwards and backwards to the level of the neck of the mandible, it terminates, between that portion of bone and the upper part of the antero-medial surface of the parotid gland, by dividing into two terminal branches—the superficial temporal and the internal maxillary arteries. At its commencement it lies anterior and medial to the internal carotid artery; and it is called external because it is distributed mainly to the parts on the exterior of the skull. It is, at first, comparatively superficial in the upper part of the carotid triangle; next, it passes under cover of the lower part of the postero-medial surface of the parotid gland, and the posterior belly of the digastric and the stylo-hyoid muscles. At the upper border of the stylo-hyoid it enters a groove in the medial border of the parotid, through which it passes to the upper part of the antero-medial surface of the gland, behind the neck of the mandible, where it terminates (Figs. 51, 73, 74).

Relations.—As it lies in the carotid triangle it is covered by the skin, superficial fascia and platysma, branches of the

nervus cutaneus colli and the cervical branch of the facial nerve, and the deep fascia. Beneath the deep fascia it is crossed superficially by the common facial and lingual veins

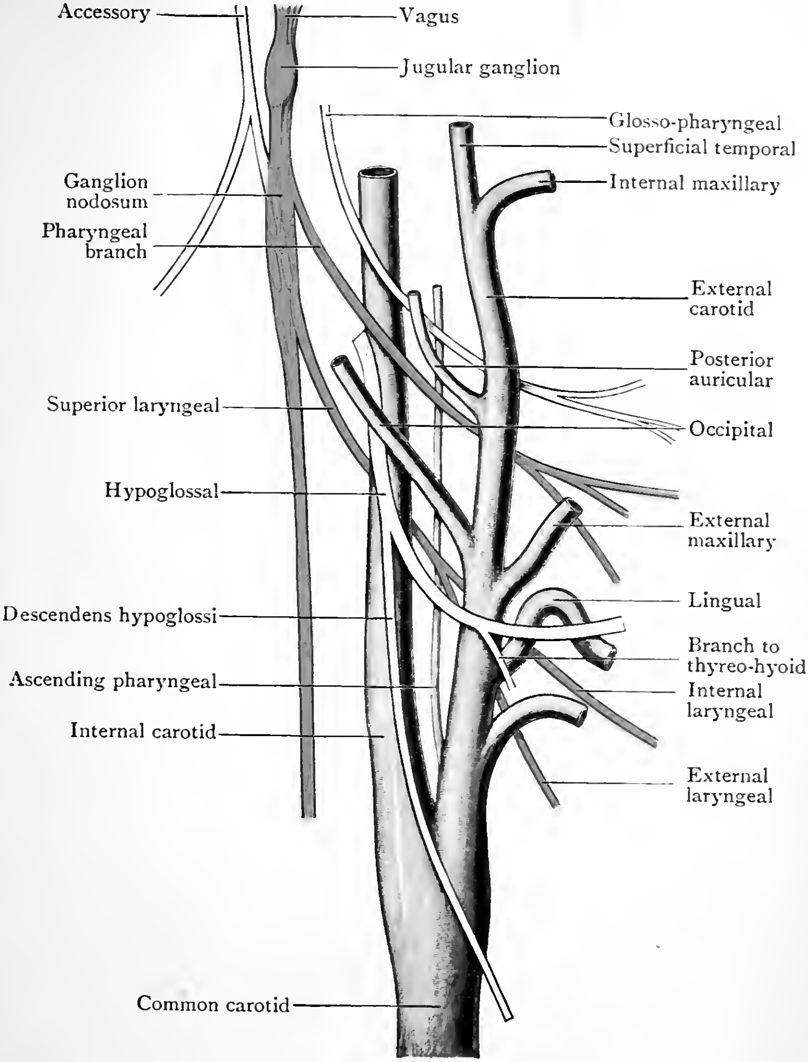

FIG. 73.—Diagram of Carotid System of Vessels in the Neck, with the Glosso-pharyngeal, Vagus, Accessory, and Hypoglossal Nerves.

and the hypoglossal nerve; and, at the upper end of the triangle, it is concealed by the lower end of the parotid gland, and it is crossed, from behind forwards, by the posterior facial vein. After it leaves the carotid triangle it is overlapped by

the angle of the mandible, and is crossed by the posterior belly of the digastric and the stylo-hyoid. At its termination it is concealed by the upper part of the parotid and is crossed by branches of the facial nerve.

To its medial side lies the wall of the pharynx with the external and internal laryngeal branches of the superior laryngeal nerve intervening in the region of the carotid triangle. The medial relations, at a higher level, will be seen to greater advantage at a later stage, when the styloid process is detached and displaced. They are the pharyngeal branch of the vagus, the stylo-pharyngeus, the glosso-pharyngeal nerve, and the styloid process or the stylo-hyoid ligament. Those structures lie to its medial side as they pass obliquely between it and the internal carotid, which has gradually attained a plane posterior and medial to that in which the external carotid lies.

In the whole of its extent the external carotid is accompanied by numerous sympathetic nerve fibres, derived from the upper cervical sympathetic ganglion; they constitute the *external carotid plexus*, which distributes offsets along all the branches of the artery.

Branches.—The branches of the external carotid artery are —the superior thyreoid, the lingual, and the external maxillary, from its anterior aspect; the occipital and the posterior auricular, from its posterior aspect; the ascending pharyngeal, from its medial side; and the superficial temporal and the internal maxillary are its terminal branches.

Arteria Thyreoidea Superior.—The superior thyreoid artery arises, within the carotid triangle, from the anterior aspect of the external carotid close to its origin. It runs downwards and forwards, under cover of the omo-hyoid, sterno-hyoid, and sterno-thyreoid muscles, to the apex of the corresponding lobe of the thyreoid gland, where it ends by breaking up into three terminal branches.

The following branches proceed from it:—

1. Hyoid.
2. Superior laryngeal.
3. Sterno-mastoid.
4. Crico-thyreoid.
5. Terminal glandular.

Ramus Hyoideus.—The hyoid branch is a small twig, which springs from the superior thyreoid in the carotid triangle. It runs along the lower border of the hyoid bone, under cover of the thyreo-hyoid muscle, and anastomoses with its fellow

of the opposite side, and with the hyoid branch of the lingual artery.

Arteria Laryngea Superior.—The superior laryngeal artery is a larger vessel. It springs from the superior thyreoid in the carotid triangle, and, associating itself with the internal laryngeal nerve, it pierces the thyreo-hyoid membrane, enters the pharynx, and descends to the larynx (Fig. 68).

Arteria Sternocleidomastoidea.—The sterno-mastoid branch is a small vessel which runs downwards and backwards, across the carotid sheath, along the upper border of the anterior belly of the omo-hyoid muscle, to reach the deep surface of the sterno-mastoid muscle, into which it sinks. It gives, in addition, minute twigs to the depressor muscles of the larynx.

Ramus Cricothyreoideus.—The crico-thyreoid artery runs medially, upon the crico-thyreoid ligament, and anastomoses with its fellow of the opposite side. It has already been noticed in the dissection of the middle line of the neck (p. 129).

Rami Glandulares.—The glandular rami are the three terminal branches. They spring from the main trunk at the apex of the lobe of the thyreoid gland. The largest branch is distributed on the medial surface of the lobe; the smallest branch ramifies on its lateral surface; whilst the third branch runs downwards upon the anterior border of the lobe, and then along the upper border of the isthmus towards its fellow of the opposite side. The medial and lateral branches are not uncommonly replaced by a posterior trunk which runs along the posterior border of the lobe. The anastomosis between the thyreoid arteries of the two sides is by no means free.

Venæ Thyreoideæ Superiores.—The superior thyreoid veins emerge from the gland and form a trunk which receives tributaries corresponding in a great measure with the branches of the artery. It crosses the upper part of the common carotid artery and joins the internal jugular vein.

Arteria Lingualis.—The lingual artery springs from the external carotid at the level of the greater cornu of the hyoid bone in the carotid triangle. It runs along the upper border of the greater cornu. As its name indicates, it is the artery of supply to the tongue. It has already been dissected in the carotid triangle and the submaxillary region, and the details of its course and relations are given on p. 197.

Arteria Maxillaris Externa (O.T. **Facial Artery**).—The

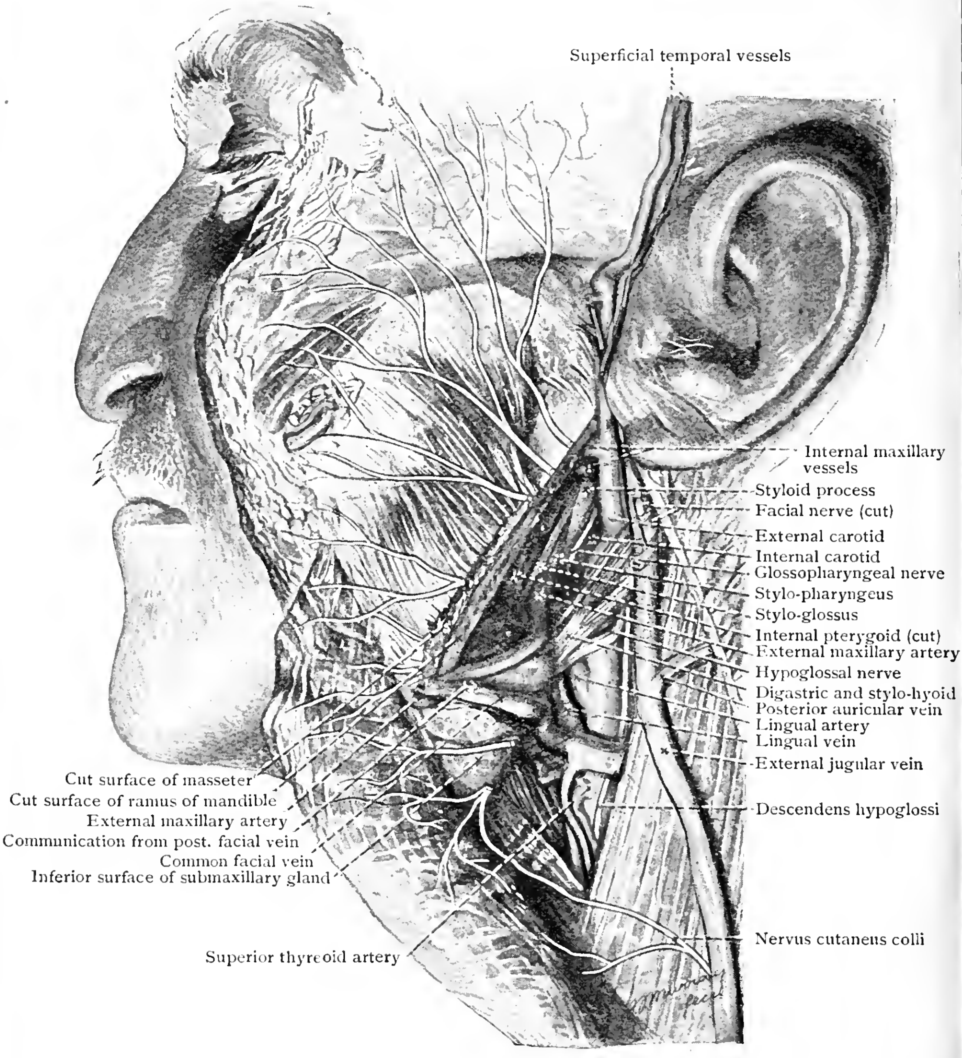

FIG. 74.—Dissection to show the relations of the External Carotid Artery and the deep part of the External Maxillary Artery. The parotid gland and the posterior part of the ramus of the mandible and the muscles attached to it have been removed. The terminal branches of the facial nerve have been cut and the terminal parts left *in situ*.

In this specimen the greater part of the posterior facial vein joined the external jugular vein. The lingual vein joined the common facial vein ; and the origin of the external maxillary artery was deep to the posterior belly of the digastric muscle.

cervical part of the external maxillary artery can be studied

at the present stage of the dissection. The artery arises from the anterior aspect of the external carotid, immediately above the lingual, in the upper part of the carotid triangle, and passes vertically upwards, on the lateral surface of the middle constrictor muscle of the pharynx, to the angle of the mandible, where it disappears under cover of the posterior belly of the digastric and the stylo-hyoid muscle. At that point the superior constrictor is medial to it and separates it from the palatine tonsil. At the upper border of the stylo-hyoid it enters a deep groove in the posterior part of the submaxillary gland, in which it runs downwards and forwards between the lateral surface of the gland and the internal pterygoid muscle, then turning round the lower border of the mandible at the anterior border of the masseter it enters the face (Fig. 74). For details of its course in the face see p. 16.

The named branches which spring from the external maxillary artery before it enters the face are:—

1. Ascending palatine.
2. Tonsillar.
3. Glandular.
4. Submental.

Arteria Palatina Ascendens.—The ascending palatine branch is given off for the supply of the soft palate, but it distributes branches to the palatine tonsil and auditory (O.T. Eustachian) tube also. It ascends between the stylopharyngeus and stylo-glossus muscles, and will be better seen when the styloid process is reflected (p. 210).

Ramus Tonsillaris.—The tonsillar branch runs upwards between the internal pterygoid and stylo-glossus muscles, then turns medially, pierces the superior constrictor, and enters the palatine tonsil.

The *glandular branches* are given to the submaxillary gland, as the external maxillary artery passes through it.

Arteria Submentalis.—The submental artery is a branch of some size. It arises close to the lower border of the mandible, and runs towards the chin, superficial to the mylohyoid muscle. Near the symphysis it changes its direction, and is carried upwards over the lower border of the mandible, to end in branches for the muscles and integument of the chin and lower lip. In the submaxillary region it gives numerous twigs to the surrounding muscles and glands, and anastomoses with the sublingual artery by branches which

pierce the mylo-hyoid muscle. It anastomoses, in the face, with the inferior labial branches of the external maxillary and the mental branch of the inferior alveolar.

Vena Facialis Anterior.—The *cervical portion* of the anterior facial vein has already been seen (p. 130) passing backwards and downwards, superficial to the submaxillary

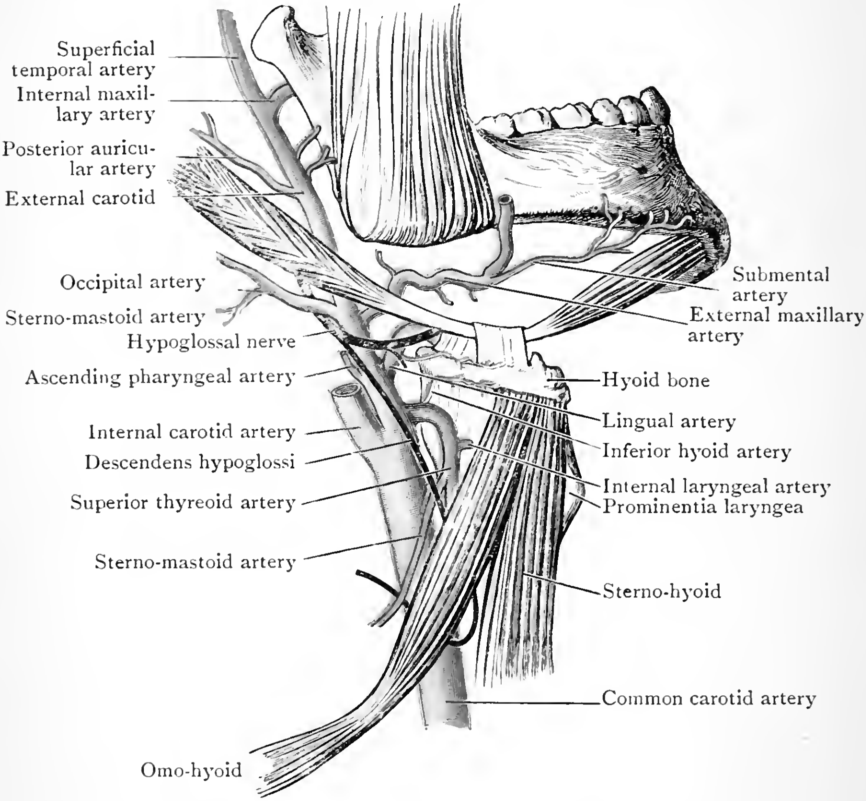

FIG. 75.—Diagram of the External Carotid Artery and its Branches. The right half of the mandible is tilted up.

gland. After receiving tributaries corresponding to the branches of the corresponding part of the external maxillary artery, it joins the posterior facial vein. The short trunk thus formed is termed the *common facial vein*, and it pours its blood into the internal jugular at the level of the hyoid bone.

Arteria Occipitalis.—The occipital artery springs from the posterior aspect of the external carotid artery, at the same level as the external maxillary. It takes the lower border of the posterior belly of the digastric muscle as its guide, and runs

upwards and backwards, under cover of the sterno-mastoid muscle, and, generally, under cover of the lower border of the posterior belly of the digastric, to reach the interval between the mastoid portion of the base of the skull and the transverse process of the atlas. Thence onwards, it has been studied in the dissection of the scalp and the back of the neck (pp. 47, 56). The first part of the vessel crosses the internal carotid artery, the vagus nerve, the accessory nerve, the internal jugular vein, and the hypoglossal nerve, which hooks round it.

The only branches which spring from the occipital artery in the region under consideration are: (1) muscular twigs; and (2) a meningeal branch.

The *muscular twigs* are given to the neighbouring muscles. One of them, the *sterno-mastoid branch*, is larger than the others and very constant, runs parallel with the accessory nerve, and sinks, with it, into the substance of the sterno-mastoid muscle.

A *meningeal branch* associates itself with the internal jugular vein, and can be followed upwards upon it to the jugular foramen, through which it passes into the cranium.

Arteria Auricularis Posterior.—The posterior auricular artery will be found above the level of the posterior belly of the digastric, and, like the occipital, it takes origin from the posterior aspect of the external carotid artery. In the first part of its course it is placed deeply, and runs upwards and backwards, between the styloid process of the temporal bone and the postero-medial surface of the parotid gland, to reach the interval between the mastoid process and the back of the auricle. Then it accompanies the posterior auricular nerve in the superficial fascia of the scalp, where its course has already been studied, in the dissection of the scalp (p. 47).

As it runs upwards and backwards the posterior auricular artery gives off (1) muscular twigs; (2) a few branches to the parotid gland; and (3) the stylo-mastoid artery.

Arteria Stylomastoidea.—The stylo-mastoid artery is a slender vessel which enters the stylo-mastoid foramen. In the interior of the temporal bone it has an extensive distribution. It supplies twigs to the mastoid cells and to the tympanic cavity, and is carried onwards, in the canalis facialis (O.T. Fallopian), to anastomose with the petrosal branch of the middle meningeal.

Arteria Maxillaris Interna.—The commencement of the internal maxillary artery, from the termination of the external carotid, between the neck of the mandible and the antero-medial surface of the parotid gland, has been seen already, and the artery has been traced through the infratemporal region to the pterygo-palatine fossa, where its terminal branches will be dissected at a later period.

Arteria Temporalis Superficialis. — Like the internal maxillary, the superficial temporal artery commences between the neck of the mandible and the antero-medial surface of the parotid gland. It passes upwards, and, as it emerges from under cover of the upper end of the parotid gland, it pierces the parotid fascia, crosses superficial to the posterior end of the zygomatic arch, and enters the superficial fascia of the scalp, in which it ascends, on the superficial surface of the temporal fascia, and anterior to the auricle (Figs. 51, 76). It breaks up into two branches, *frontal* and *parietal.* The two branches anastomose with each other and with their fellows of the opposite side. The frontal branch anastomoses with the supra-orbital and frontal branches of the ophthalmic also, and the parietal branch anastomoses with the posterior auricular and the occipital arteries. Whilst it is still under cover of the parotid it gives branches to the gland; *anterior auricular branches* to the auricle; the *transverse facial*, which passes along the lower border of the zygomatic arch, across the masseter. As the superficial temporal crosses the zygoma it gives off a *zygomatico-orbital branch*, which runs to the lateral border of the orbit, and a *middle temporal branch*, which perforates the temporal fascia and anastomoses in the temporal fossa with the deep temporal branches of the internal maxillary. The course of the middle temporal branch (Fig. 76) and the distribution of the terminal branches have been followed in earlier stages of the dissection (pp. 48, 169).

Dissection.—Divide the posterior belly of the digastric immediately below its origin, and turn it downwards and forwards towards the hyoid bone; then examine the stylo-pharyngeus muscle. It may be necessary to cut the occipital and posterior auricular arteries in order to gain free access to the deeper parts, but that should not be done unless it is unavoidable. Care must be taken whilst cleaning the stylo-pharyngeus to avoid injuring the glosso-pharyngeal nerve, which turns round its posterior border and crosses its superficial surface.

Musculus Stylopharyngeus.—The stylo-pharyngeus is the longest of the three slender muscles which spring from the styloid process. It arises from the deep or medial surface of the process, close to its root, and extends downwards and

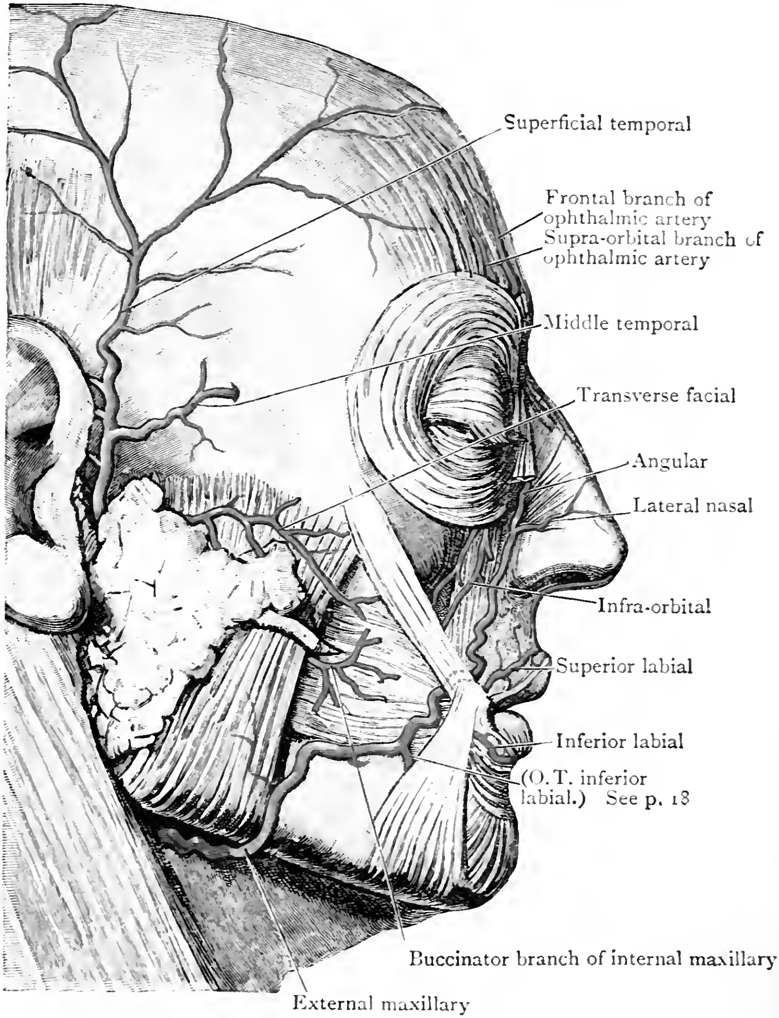

FIG. 76.—Arteries of the Face.

forwards to gain the side of the pharynx, where it disappears under cover of the upper border of the middle constrictor muscle. Whilst under cover of the middle constrictor its fibres blend with those of the pharyngo-palatinus, and, with them, are inserted into the posterior border of the corresponding lamina of the thyreoid cartilage. It is supplied

by the glosso-pharyngeal nerve. If the dissector removes the fascia at the posterior part of the thyreo-hyoid space he will expose the lower fibres of the middle and the upper fibres of the inferior constrictor, and in the interval between them, on a deeper plane, the lateral surface of the lower part of the stylo-pharyngeus. It is an elevator of the larynx.

Dissection.—Snip through the base of the styloid process with the bone forceps, and throw it and the attached muscles downwards and forwards. The upper parts of the internal carotid artery and internal jugular vein are now exposed, and the ascending pharyngeal and ascending palatine arteries can be followed to the base of the skull.

If the external carotid is pushed forwards and the internal carotid is pulled backwards the ascending pharyngeal artery will be seen, in a well-injected subject, lying in the areolar tissue between the two carotid arteries and on a deeper plane. It must be cleaned and followed to the base of the skull.

Arteria Pharyngea Ascendens.—The ascending pharyngeal artery springs from the medial surface of the external carotid artery, close to its lower end, and is its smallest branch. It ascends along the lateral border of the pharynx, lying between the stylo-pharyngeus laterally and the constrictors of the pharynx medially, first in a plane between the external and internal carotid arteries, and then to the medial side of the internal carotid. As it passes upwards it gives *pharyngeal branches* to the wall of the pharynx, and *prevertebral branches* to the prevertebral muscles. At the base of the skull it gives off *meningeal branches*, which enter the cranial cavity through the hypoglossal canal, the jugular foramen, and the foramen lacerum; and *palatine branches*, which pierce the pharyngeal aponeurosis, above the upper border of the superior constrictor, and descend, along the levator veli palatini, to the soft palate. Offsets from the latter branches are given to the auditory tube (O.T. Eustachian) and to the palatine tonsil.

Arteria Palatina Ascendens.—After the ascending palatine artery has passed between the stylo-glossus and the stylo-pharyngeus (see p. 205), it ascends, along the side of the pharynx, to the petrous part of the temporal bone. There it pierces the pharyngeal aponeurosis, and then it accompanies the levator veli palatini to the soft palate. It helps to supply the soft palate, the palatine tonsil, the wall of the pharynx, and the auditory tube.

Dissection.—After the ascending pharyngeal artery has been examined, the *internal carotid artery*, the *glosso-pharyngeal, vagus, accessory*, and *hypoglossal nerves*, and the *superior cervical ganglion*, with their various connections and branches, must be dissected. A dense and tough fascia envelops them, and a great amount of patience is required to trace the branches of the nerves through it. One nerve—*the pharyngeal branch of the vagus*—which proceeds downwards and forwards, upon the superficial or lateral aspect of the internal carotid, is especially liable to injury, and must therefore be borne in mind from the very outset of the dissection. The *internal laryngeal* and the *external laryngeal nerves* have been previously displayed in the anterior triangle of the neck. If they are traced upwards, they will lead to the *superior laryngeal branch* of the vagus, which lies in relation with the deep aspect of the internal carotid artery. Near the base of the skull all the nerve-trunks will be found making their appearance, close together, in the interval between the internal jugular vein and the internal carotid artery; whilst posterior to the vein the *rectus lateralis muscle* and the *first loop* of the *cervical plexus* will be seen.

Arteria Carotis Interna.—The internal carotid artery is one of the two terminal branches of the common carotid, and it commences, therefore, at the level of the upper border of the thyreoid cartilage. From that point it proceeds upwards in the neck, in a vertical direction, until it reaches the base of the skull; there it disappears from view by entering the carotid canal of the petrous portion of the temporal bone. Through the carotid canal it reaches the interior of the cranium. The internal carotid artery can therefore be very appropriately divided into three parts—viz., (1) a cervical; (2) a petrous; and (3) an intracranial. The cervical part alone comes under the notice of the student in the present dissection.

In the first part of its extent the internal carotid artery lies in the carotid triangle, and is therefore comparatively superficial. It is covered by the integument, platysma, and fascia, and is overlapped by the sterno-mastoid muscle and the anterior border of the internal jugular vein. It is crossed by the hypoglossal nerve, the occipital artery and its sterno-mastoid branch, and the lingual and common facial veins. The descendens hypoglossi descends on its superficial surface.

As it proceeds upwards, it passes under cover of the lower end of the parotid gland and then at a higher level under cover of the posterior belly of the digastric, the stylo-hyoid, the stylo-pharyngeus, and the styloid process, which separate it from the postero-medial surface of the parotid gland. It

will be noted also that *three nerves* and *three arteries* cross the vessel superficially, viz. :—

1. The hypoglossal nerve.
2. The glosso-pharyngeal nerve.
3. The pharyngeal branch of the vagus nerve.

1. The occipital artery.
2. The sterno-mastoid branch of the occipital artery.
3. The posterior auricular artery.

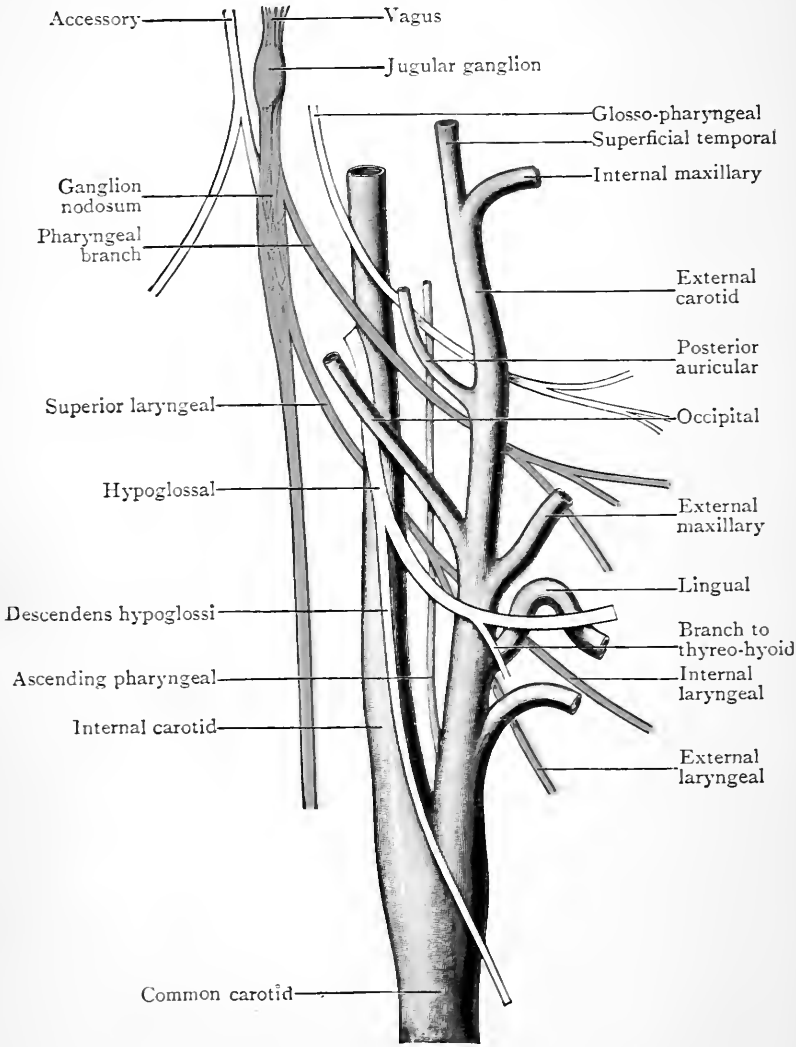

FIG. 77.—Diagram of Carotid System of Vessels in the Neck, with the Glosso-pharyngeal, Vagus, Accessory, and Hypoglossal Nerves.

The hypoglossal nerve, as already noted, crosses it in the carotid triangle; the other nerves cross it under cover of the posterior belly of the digastric. The occipital artery crosses

it at the level of the lower border of the posterior belly of the digastric, the posterior auricular, at the level of the upper border of that muscle, and the sterno-mastoid branch of the occipital artery at the point where the hypoglossal nerve turns forwards.

The relationship of the external carotid artery to the internal carotid is a varying one. At first the external carotid lies antero-medial to the internal carotid; but soon, owing to its inclination backwards, it comes to lie superficial to the internal carotid. The following structures intervene between the two vessels:—

1. Styloid process.
2. Stylo-pharyngeus muscle.
3. Glosso-pharyngeal nerve.
4. Pharyngeal branches of vagus and sympathetic.
5. A portion of the parotid gland.

Posterior to the internal carotid are the longus capitis (O.T. rectus capitis anticus major) and the sympathetic trunk; postero-laterally are the glosso-pharyngeal, the vagus, the accessory and the hypoglossal nerve; and still more laterally and posteriorly is the internal jugular vein. On its *medial aspect* the internal carotid is related to the constrictors of the pharynx, the ascending pharyngeal artery and the levator veli palatini.

Before leaving the internal carotid artery, note that, near the base of the skull, four nerves appear in the interval between it and the internal jugular vein; they are the glosso-pharyngeal, the vagus, the accessory, and the hypoglossal.

Vena Jugularis Interna.—The internal jugular vein is the largest venous channel of the neck. It enters the neck through the postero-lateral compartment of the jugular foramen, where it is directly continuous with the transverse blood sinus of the cranium. From the jugular foramen it proceeds downwards, until it reaches the posterior aspect of the medial end of the clavicle, where it joins the subclavian vein to form the innominate vein (Fig. 78). Its commencement in the jugular foramen shows a slight dilatation, termed *the bulb*, the lumen of which remains at all times patent owing to the connection of walls of the bulb to the margins of the foramen. The skull cap should be removed and a probe should be passed from the transverse sinus into the internal jugular vein, to demonstrate the continuity of the two channels.

Relations.—At its commencement the internal jugular

PLATE VII

FIG. 78.—Dissection of the Head and Neck of the same subject as that shown in Fig. 15, but the greater part of the parotid gland, the greater part of the sterno-mastoid muscle, the greater part of the external jugular vein, portions of other veins, portions of the sterno-hyoid and sterno-thyreoid muscles, and the submaxillary gland have been removed to display deeper structures.

1. Supra-orbital artery and nerve.
2. Frontal artery and vein.
3. Lateral nasal branch of external maxillary artery.
4. Superior labial branch of external maxillary artery.
5. Inferior labial branch of external maxillary artery.
6. External maxillary artery.
7. External maxillary artery.
8. Deep part of submaxillary gland.
9. Lingual artery.
10. Submental branch of external maxillary artery.
11. Mylo-hyoid muscle.
12. Nerve to thyreo-hyoid muscle.
13. Internal laryngeal nerve.
14. Common facial vein.
15. Superior thyreoid vessels.
16. Common carotid artery and descendens hypoglossi nerve.
17. Sterno-hyoid muscle.
18. Omo-hyoid muscle (anterior belly).
19. Sterno-thyreoid muscle.
20. Thyreoid gland.
21. Middle thyreoid vein.
22. Trachea.
23. Inferior thyreoid vein.
24. Sterno-thyreoid muscle.
25. Sterno-hyoid muscle.
26. Subclavius muscle with nerve.
27. Cephalic vein.
28. Lateral anterior thoracic nerve.
29. Acromial branch of thoraco-acromial artery.
30. Transverse scapular vessels.
31. First serration of serratus anterior muscle.
32. Subclavian artery.
33. Transverse cervical artery.
34. Upper root of long thoracic nerve.
35. Trapezius.
36. Scalenus anterior.
37. Internal jugular vein.
38. Communicans hypoglossi nerve.
39. Ascending branch of transverse cervical artery.
40. Internal carotid artery.
41. External carotid artery.
42. Hypoglossal nerve.
43. Occipital artery and sterno-mastoid branch.
44. Lesser occipital nerve.
45. Digastric and stylo-hyoid muscles.
46. Third occipital nerve.
47. Greater occipital nerve and occipital artery.
48. Posterior auricular artery and vein.
49. Superficial temporal vessels and auriculo-temporal nerve.

PLATE VII

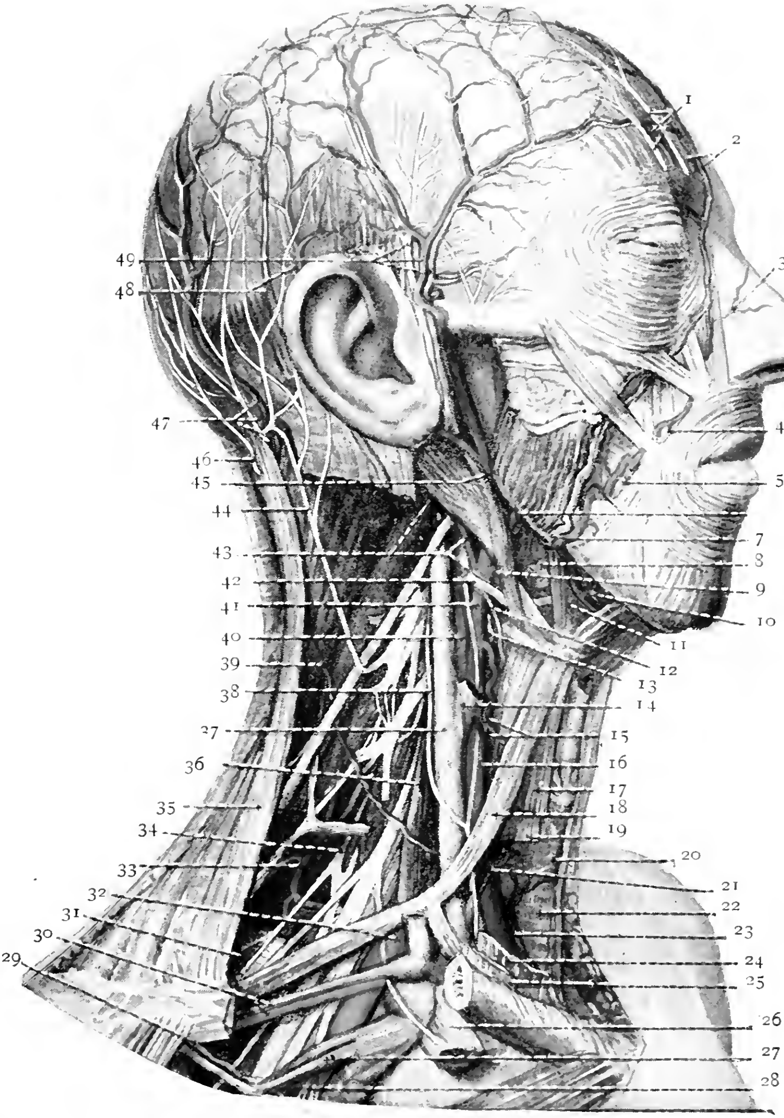

FIG. 78.

vein lies postero-lateral to the upper end of the cervical part of the internal carotid artery, from which it is partially separated by the last four cerebral nerves. As it descends it assumes a more directly lateral relationship, first to the internal carotid and then to the common carotid, overlapping each vessel to a slight extent anteriorly; and it is enclosed, with them and the vagus nerve, in a common sheath of deep cervical fascia, the nerve lying in its own compartment of the sheath between the vein laterally and the arteries medially, and in a posterior plane (Figs. 47, 48, 53).

The superficial or lateral relations of the vein in the upper part of its extent are the styloid process, with the stylo-

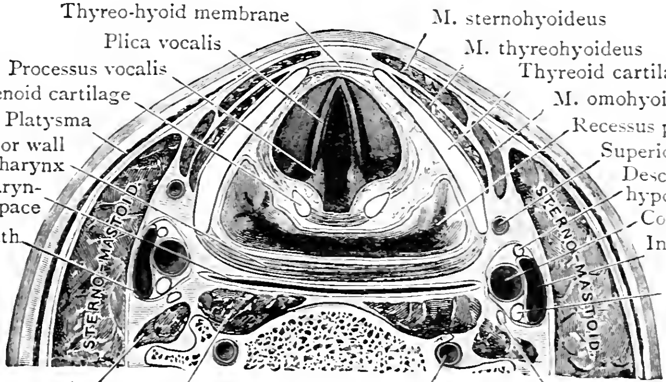

FIG. 79.—Transverse section through the Neck at the level of upper part of Thyreoid Cartilage.

pharyngeus and stylo-hyoid muscles, and the posterior belly of the digastric, which separate it from the upper part of the postero-medial surface of the parotid gland. In that part of its extent it is crossed superficially, along the upper border of the posterior belly of the digastric, by the posterior auricular artery, and at the lower border of the digastric by the accessory nerve, passing downwards and backwards, and by the occipital artery, passing upwards and backwards, superficial to the nerve. At a slightly lower level it is concealed by the lower part of the postero-medial surface of the parotid, and it is crossed by the sterno-mastoid branch of the occipital artery. After it emerges from under cover of the parotid, it lies under cover of the anterior border of the

sterno-mastoid, except in the region of the upper part of the carotid triangle, where it may project forwards, beyond the anterior border of the muscle, for a short distance. It is separated from the sterno-mastoid by numerous deep cervical lymph glands; and under cover of the muscle it is crossed superficially, at the level of the upper part of the thyreoid cartilage, by the communicans cervicalis from the cervical plexus, and, at the level of the cricoid cartilage, by the intermediate tendon of the omo-hyoid, the sterno-mastoid branch of the superior thyreoid artery and the nerve to the posterior belly of the omo-hyoid. Below the omo-hyoid it is covered by the posterior border of the sterno-hyoid, and is

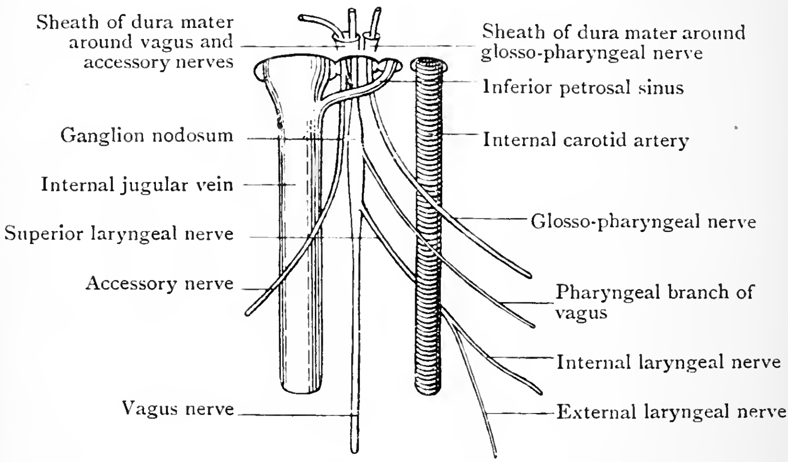

FIG. 80.—Diagram of the relation of parts in the Jugular Foramen.

crossed by the anterior jugular vein; and at its termination it lies posterior to the sternal end of the clavicle.

Posteriorly, it is in relation with the rectus capitis lateralis; the rectus capitis anterior (O.T. anticus minor); and the loop between the first and second cervical nerves. At a lower level its posterior relations are the transverse processes of the cervical vertebræ and the muscles attached to their anterior tubercles, viz., the longus capitis (O.T. rectus capitis anticus major) and the scalenus anterior. Between its posterior surface and the scalenus anterior are the ascending cervical artery, the phrenic nerve, and, crossing superficial to the latter, the transverse cervical and the transverse scapular arteries. On the left side the terminal part of the thoracic duct also

crosses the phrenic nerve posterior to the internal jugular vein. At the medial border of the scalenus anterior the thyreo-cervical trunk is posterior to it, and, at a lower level, the first part of the subclavian artery and the dome of the pleura.

The right vein is usually the larger of the two; and as they approach the root of the neck both veins incline slightly to the right, with the result that, on the right side, the lower part of the vein is separated from the common carotid artery by a small triangular interval bounded below by the subclavian artery, whilst on the left side the vein overlaps the anterior aspect of the common carotid artery.

Tributaries.—Immediately below its commencement the internal jugular vein is joined by the inferior petrosal sinus, and then, successively, by offsets from the pharyngeal plexus, by the lingual veins, the common facial vein, and the superior and middle thyreoid veins. In some cases it is joined near its upper end by a *vena comitans* which runs with the occipital artery; and, occasionally, near its lower end, it receives the lymph trunks which usually open into the commencement of the innominate vein.

Dissection.—Slit open the lower part of the vein and examine the valve which lies close to its extremity. It consists of two or three semilunar flaps which prevent regurgitation of blood from the innominate vein into the internal jugular.

Nervi Glosso-pharyngeus, Vagus et Accessorius.—After the removal of the brain the glosso-pharyngeal, vagus, and accessory nerves were seen leaving the cranial cavity, through the middle compartment of the jugular foramen, in the interval between the commencement of the internal jugular vein postero-laterally and the inferior petrosal sinus antero-medially (p. 111, and Fig. 81, p. 218). The dissector should again examine the interior of the cranial cavity and refresh his memory as to the manner in which the nerves enter the foramen. The *glosso-pharyngeal* occupies the most anterior position, and it is cut off from the others by a separate, tube-like sheath of dura mater. The *accessory* is placed posterior to the *vagus*, and both are included within the same sheath of dura mater. They therefore traverse the foramen in close contact with each other. Reaching the exterior of the skull, the three become associated with the hypoglossal nerve; and the four nerves lie, for a short distance, in the interval between the internal jugular vein

and the internal carotid artery, but soon they choose different routes. The *accessory* inclines backwards, superficial or deep to the internal jugular vein; the *glosso-pharyngeal* runs forwards, superficial to the internal carotid, and under cover of the posterior belly of the digastric; at a lower level, the hypoglossal also turns forwards across the internal and external carotid arteries; and the *vagus* proceeds

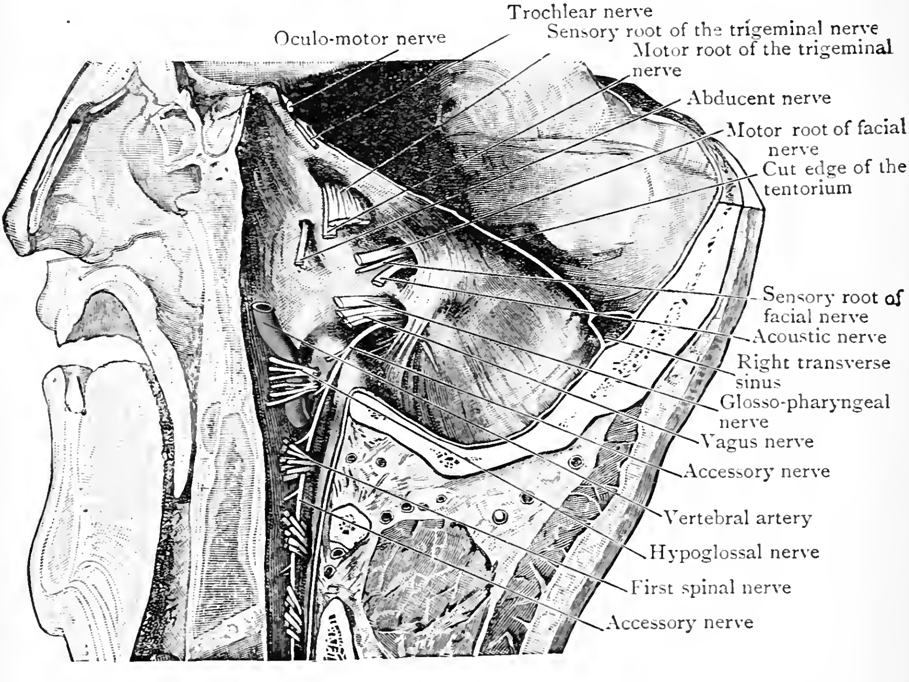

FIG. 81.—Section through the Head a little to the right of the Median Plane. It shows the posterior cranial fossa and the upper part of the vertebral canal after the removal of the brain and the medulla spinalis.

vertically downwards, first between the internal jugular vein and the internal carotid artery, and then between the vein and the common carotid artery (Fig. 79).

In an ordinary dissection it is impossible to follow out many of the minute twigs which take origin from the last four cerebral nerves in the region of the basis cranii. To do so it is necessary to possess a perfectly fresh part which has been specially prepared by having the soft parts toughened with spirit and the bone softened by immersion in a weak solution of acid. Even then the dissection is a difficult one, but it should be undertaken by the advanced student, in the event of his being able to obtain a part for the purpose.

In the following description of the nerves the account of the branches which can in all cases be traced is printed in *ordinary type*, whilst that of those requiring special dissection is printed in *small type.*

Nervus Glosso-pharyngeus.—The glosso-pharyngeal nerve inclines downwards and forwards and crosses the internal carotid artery superficially. At first it lies medial to the styloid process and the stylo-pharyngeus muscle, then it hooks round the lower border of the muscle and curves forwards across its superficial surface to gain the base of the tongue. In the dissection of the submaxillary region, its terminal part was seen disappearing under cover of the hyoglossus muscle, where it ends in *lingual branches* (Fig. 68).

In the present dissection an attempt should be made to secure the following branches:—

1. Communicating branch from the facial.
2. Nerve to the stylo-pharyngeus.
3. Pharyngeal.
4. Tonsillar.
5. Lingual.

The *communicating branch from the facial* springs from the nerve to the posterior belly of the digastric, and, as a rule, emerges from amidst the fibres of that muscle to join the glosso-pharyngeal close to the lower part of the jugular foramen.

The *stylo-pharyngeal nerve* is a small twig which enters the muscle of the same name. The greater part of its fibres, however, are continued through the muscle to the mucous membrane of the pharynx.

The *pharyngeal branches* consist of—(1) one or two small twigs which perforate the superior constrictor to reach the mucous membrane of the pharynx; and (2) a larger nerve which comes off higher up and passes with the pharyngeal branch of the vagus to the pharyngeal plexus. It frequently divides into two or more branches.

The *tonsillar branches* proceed from the glosso-pharyngeal near the base of the tongue. They form a plexus, over the palatine tonsil, termed the *circulus tonsillaris*, and give twigs to the mucous membrane of the isthmus faucium and the soft palate as well as to the tonsil.

The *terminal* or *lingual branches* will be followed in the dissection of the tongue.

There are still other points in connection with the glosso-pharyngeal nerve which require mention. At the lower part of the jugular foramen two small ganglia are formed upon its trunk, and from the lower of the two

certain minute branches are given off. The upper ganglion is called the *ganglion superius*; the lower one is termed the *ganglion petrosum*.

The *superior ganglion* is a small ganglionic swelling, which involves only a portion of the fibres of the nerve trunk. It is placed in the upper part of the bony groove in which the nerve lies as it proceeds through the jugular foramen. No branches arise from it.

The *petrous ganglion* is a larger swelling, which involves the entire nerve-trunk, and lies at the opening of the jugular foramen, between the vagus nerve and the inferior petrosal sinus (which intervenes between it and the anterior border of the foramen). Its length is not more than four or five millimetres. Three branches of communication enter or proceed from it and connect it with—(1) the superior cervical sympathetic ganglion; (2) the auricular branch of the vagus; and (3) the jugular ganglion of the vagus.

In addition to the twigs mentioned, the *tympanic nerve* takes origin from the petrous ganglion.

Nervus Tympanicus.—The ultimate destination of the tympanic nerve may be regarded as the otic ganglion, but it takes a very circuitous route to gain that structure, and it gives off branches on the way. It enters a small foramen on the ridge which separates the jugular fossa from the carotid foramen on the lower surface of the petrous bone, and it is conducted by a narrow canal to the tympanic cavity. It crosses the medial wall of that chamber, grooving the promontory. Having gained the anterior part of the tympanum, it enters the bone a second time, and runs in a minute canal, which tunnels the petrous bone below the upper end of the channel which lodges the tensor tympani muscle. In that part of its course the tympanic nerve is joined by a branch from the ganglion geniculi of the facial nerve, and, after the junction is effected, it is termed the *lesser superficial petrosal nerve*.

The canal in which the *lesser superficial petrosal nerve* is lodged opens, by a small aperture, into the cranial cavity, upon the anterior surface of the petrous bone, immediately lateral to the hiatus canalis facialis. Through the aperture the nerve enters the cranial cavity, and it almost immediately leaves it by passing downwards in the interval between the great wing of the sphenoid and the petrous part of the temporal bone, or through the canaliculus innominatus, or through the foramen ovale. Outside the skull it joins the otic ganglion.

In the tympanic cavity the *tympanic nerve* gives branches of supply —(1) to the mucous membrane of the tympanum; (2) to the lining membrane of the mastoid cells; and (3) to the mucous membrane of the auditory tube (Eustachian). It is connected with the sympathetic plexus on the internal carotid artery by the *superior* and *inferior carotico-tympanic branches* which pierce the substance of the petrous part of the temporal bone and form with the tympanic nerve the *tympanic plexus*.

Nervus Vagus.—The vagus nerve passes through the middle compartment of the jugular foramen in company with the accessory nerve—both being included within the same sheath of dura mater. In the neck, it pursues a vertical course, lying, at first, between the internal jugular vein and the internal carotid artery, and afterwards between the same vein and the common carotid artery, enclosed within the sheath which envelops the vessels, but on a plane posterior

to them. Its posterior relations, therefore, are similar to those of the common and internal carotid arteries (pp. 117, 211). At the root of the neck it enters the thorax, and has different relations on the two sides. On the *right side* it crosses the first part of the subclavian artery; on the *left side*, after crossing anterior to the thoracic duct, it proceeds downwards between the left common carotid and subclavian arteries, posterior to the left innominate vein. For its thoracic relations see Vol. II. p. 127.

The vagus, like the glosso-pharyngeal, has two ganglia in connection with its upper part. These are the *ganglion jugulare* and the *ganglion nodosum*.

Ganglion Jugulare (O.T. **Ganglion of Root**).—The jugular ganglion is situated within the jugular foramen. It is a rounded swelling which is connected by communicating twigs with several of the nerves in the neighbourhood, and it gives off two branches of distribution.

Branches of Communication.—(1) With the facial nerve; (2) with the petrous ganglion of the glosso-pharyngeal; (3) with the accessory; (4) with the superior ganglion of the sympathetic.

Branches of Distribution.—(1) Meningeal; (2) Auricular nerve.

The *meningeal branch* is a minute twig which runs upwards through the jugular foramen, and, dividing into two branches, is distributed to the dura mater in the posterior cranial fossa.

The *auricular nerve* (O.T. Arnold's nerve) obtains a filament of communication from the petrous ganglion of the glosso-pharyngeal, and passes backwards, upon the lateral surface of the bulb of the internal jugular vein, to enter a minute aperture on the posterior part of the lateral wall of the jugular fossa. A narrow canal then conducts it through the substance of the temporal bone, and, on its way, it crosses the canalis facialis a short distance above the stylo-mastoid foramen. It is thus brought into close relation with the facial nerve and is connected with it by an ascending and a descending branch of communication. Finally, it appears on the surface of the skull, in the interval between the mastoid process and the external acoustic meatus, where it communicates with the posterior auricular branch of the facial. It supplies the skin on the posterior aspect of the outer surface of the wall of the meatus, the skin covering the lower half of the inner surface of the wall of the meatus, and the lower half of the tympanic membrane.

Ganglion Nodosum.—After emerging from the jugular foramen, the vagus nerve is joined by the *cerebral portion* of the *accessory nerve*, and swells out into the ganglion nodosum (O.T. ganglion of trunk).

The *ganglion nodosum* is an elongated reddish-coloured swelling, about 18 mm. (three-quarters of an inch) in length, which is developed upon the stem of the vagus, 12.5 mm. (half an inch) below the base of the cranium. Strong branches of communication pass between it and the first

loop of the cervical plexus, and the superior cervical ganglion of the sympathetic. Further, the hypoglossal nerve is generally closely bound to it by fibrous attachment, in the midst of which some interchange of nerve filaments takes place.

Branches of Distribution of the Cervical Part of the Vagus.—The branches which spring from the vagus as it traverses the neck are the following: (1) pharyngeal; (2) superior laryngeal; (3) recurrent; (4) cardiac.

Ramus Pharyngeus.—The pharyngeal branch springs from the upper part of the ganglion nodosum and runs downwards and forwards, superficial to the internal carotid artery, to end in the *pharyngeal plexus*. It is frequently replaced by two branches, of which the upper is the larger.

Nervus Laryngeus Superior.—The superior laryngeal nerve, a much larger branch, arises from the middle of the ganglion nodosum. It passes downwards and forwards, but differs from the pharyngeal branch by passing deep to the internal carotid artery. Whilst in that situation it ends by dividing into the *internal laryngeal* and *external laryngeal nerves*, both of which have been previously seen in the dissection of the anterior triangle (p. 132).

Before it divides, the superior laryngeal effects communications, by means of fine twigs, with the superior cervical ganglion of the sympathetic, and it also receives one or two filaments from the pharyngeal plexus.

The *internal laryngeal nerve* runs to the interval between the hyoid bone and the thyreoid cartilage; there, after disappearing under cover of the posterior border of the thyreo-hyoid muscle, it pierces the membrane of the same name, and enters the pharynx, and then descends to the larynx.

The *external laryngeal nerve* is a very slender branch, which inclines downwards and forwards to reach the crico-thyreoid muscle, in which it ends.

It supplies a few filaments to the inferior constrictor of the pharynx and a fine twig to the superior cardiac branch of the sympathetic, whilst it receives a communicating branch from the superior cervical ganglion of the sympathetic.

Nervus Recurrens.—The recurrent nerve arises differently on the two sides. On the *right side*, after springing from the vagus as the latter crosses the first part of the subclavian artery, it hooks round the artery and ascends to its termination. On the *left side*, it arises from the vagus,

in the thorax, and hooks round the aortic arch. In the neck, each recurrent nerve ascends in the groove between the trachea and œsophagus, along the medial side of the corresponding lobe of the thyreoid gland, and, passing posterior or anterior to the inferior thyreoid artery, it disappears, as *the inferior laryngeal nerve*, under cover of the lower border of the inferior constrictor muscle, and enters the larynx.

Before the recurrent nerve reaches the larynx it gives off several branches — viz., (1) cardiac branches; (2) twigs to the trachea and œsophagus; and (3) a few filaments to the inferior constrictor, as it passes under cover of its lower margin.

Cardiac Branches.—Two cardiac branches arise from the vagus in the neck. On the *right side*, both of them enter the thorax by passing posterior to the subclavian artery, and they end in the deep cardiac plexus. On the *left side*, the *upper nerve* joins the deep cardiac plexus, whilst the *lower nerve* enters into the formation of the superficial cardiac plexus.

Nervus Accessorius.—The accessory nerve consists of two parts—a *spinal* and a *cerebral*. In the jugular foramen the *cerebral portion* is connected by one or two fine twigs with the jugular ganglion of the vagus, and below the base of the skull it leaves the spinal part and joins the vagus.

The *cerebral part* of the accessory nerve contributes to the vagus the greater proportion of its motor fibres. They pass over the surface of the ganglion nodosum, and are continued into the pharyngeal and into the superior laryngeal nerves. Some of the fibres are carried down the stem of the vagus into the cardiac branches and also into the recurrent nerve.

The *spinal part* of the accessory is directed backwards below the level of the transverse process of the atlas. It crosses the internal jugular vein, and disappears into the sterno-mastoid muscle. Its further course has been studied already (pp. 41 and 133). It is distributed to two muscles —viz., the sterno-mastoid and the trapezius.

Plexus Pharyngeus.—The pharyngeal plexus is a meshwork of fine nerve filaments, which is formed upon the wall of the pharynx at the level of the middle constrictor muscle. The pharyngeal branches of the vagus, glosso-pharyngeal, and superior cervical ganglion of the sympathetic enter into its construction, and one or more minute ganglia are developed in connection with it. Its terminal twigs are given

to the muscles and mucous membrane of the pharynx, and one branch (the *ramus lingualis vagi*) connects the plexus with the hypoglossal nerve.

Nervus Hypoglossus.—The hypoglossal nerve makes its exit from the cranium through the hypoglossal canal (O.T. anterior condyloid foramen). It pierces the dura mater in two separate parts, which unite into one stem at the external orifice of the bony canal. As it issues from the canal it lies deeply, medial to the internal jugular vein and the internal carotid artery; immediately afterwards it inclines laterally, and, taking a half spiral turn around the ganglion nodosum of the vagus, it appears between the two vessels, and descends between them to the lower border of the posterior belly of the digastric muscle, where it passes into the carotid triangle. Its close connection with the ganglion nodosum of the vagus has been noted already (p. 221). In the carotid triangle, it hooks round the lower end of the occipital artery, below its sterno-mastoid branch, and, turning forwards, it crosses superficial to the occipital, the internal and external carotid arteries and the loop of the lingual artery. Then it passes across the medial sides of the posterior belly of the digastric and the stylo-hyoid, and enters the digastric triangle, where it disappears medial to the mylo-hyoid; and at the anterior border of the hyoglossus it enters the root of the tongue.

Branches of Communication.—Near the base of the skull the hypoglossal nerve is connected with—(1) the superior cervical ganglion; (2) the vagus; and (3) the first cervical nerve; as it turns round the occipital artery it receives (4) the *ramus lingualis vagi* from the pharyngeal plexus; and on the surface of the hyoglossus it communicates with (5) the lingual nerve by one or more branches (p. 195).

Branches of Distribution.—(1) The *meningeal branch* arises in the upper part of the canalis hypoglossi, and, regaining the interior of the cranium, it is distributed to the dura mater around the foramen magnum. (2) *Vascular twigs* are said to be supplied to the deep aspect of the internal jugular vein. (3) The *descendens hypoglossi*, which conveys fibres of the first cervical nerve to the infra-hyoid muscles. (4) The *nerve to the thyreo-hyoid*, which also consists of first cervical nerve fibres. (5) The *terminal branches*, which supply the genio-hyoid and all the intrinsic and extrinsic muscles of the tongue, except the glosso-palatinus.

Dissection.—In the preceding dissections of the neck the greater part of the cervical sympathetic, and the branches which

proceed from it, have been displayed. The inferior ganglion, which lies deeply, in the hollow between the transverse process of the seventh cervical vertebra and the neck of the first rib, is still to a certain extent concealed, and must now be displayed. Dislodge the subclavian artery from its place on the first rib behind the scalenus anterior muscle, and turn it medially. To do that efficiently, it will be necessary to cut the costo-cervical artery at its origin. Great care must be taken to preserve uninjured the fine nerves which proceed downwards anterior to the first part of the subclavian artery. If more space for the dissection is required, the anterior part of the first rib may be removed by the bone-forceps, but, as a general rule, that will not be necessary.

Truncus Sympathicus in the Neck.—The cervical part of the sympathetic trunk takes a vertical course through the neck, anterior to the roots of the transverse processes of the vertebræ. It lies between the internal and common carotid arteries anteriorly and the longus capitis (O.T. rectus capitis anticus major) and longus colli muscles posteriorly. *Above*, it is prolonged upwards in the form of a stout, ascending nerve-trunk, *the nervus caroticus internus*, which accompanies the internal carotid artery into the carotid canal; *below*, it becomes continuous, over the neck of the first rib and posterior to the apex of the pleura, with the thoracic portion of the sympathetic trunk. Only three ganglia are developed upon the cervical part of the trunk and no white rami communicantes from the cervical nerves enter either the trunk or the ganglia.

Ganglion Cervicale Superius.—The superior cervical ganglion, the largest of the three ganglia, is an elongated fusiform body which varies somewhat in size. It is placed upon the upper part of the longus capitis, opposite the second and third cervical vertebræ, and posterior to the carotid sheath. From its upper end the stout nervus caroticus internus passes into the carotid canal, whilst its lower end tapers downwards into the trunk. Numerous branches issue from it; some of them connect it with neighbouring nerves, whilst others are distributed in various ways.

The connecting branches are: (1) slender *grey rami communicantes* which connect it with the upper four cervical nerves; (2) twigs to both ganglia of the vagus; (3) to the petrous ganglion of the glosso-pharyngeal; and (4) to the hypoglossal. It is not connected with the accessory.

The branches of distribution are: (1) nervus caroticus internus; (2) nervi carotici externi; (3) rami laryngopharyngei; (4) nervus cardiacus superior.

Nervus Caroticus Internus.—The internal carotid nerve passes from the upper end of the ganglion into the carotid canal. Its distribution will be considered later (p. 241).

Nervi Carotici Externi.—Two to six filaments, called external carotid branches, run to the external carotid artery, and form a loose interlacement around it called the *external carotid plexus* from which a branch is given to the glomus caroticum, and prolongations are continued on all the branches of the artery. The part continued upon the external maxillary artery supplies the sympathetic root to the submaxillary ganglion, whilst the subdivision upon the middle meningeal artery furnishes the corresponding root to the otic ganglion, as well as the *external superficial petrosal nerve*, which runs to the ganglion geniculi of the facial nerve.

Rami Laryngo-pharyngei.—The laryngo-pharyngeal branches join the pharyngeal plexus and the superior laryngeal nerve.

Nervus Cardiacus Superior.—The superior cardiac nerve is a long slender branch which springs, by several roots, from the ganglion, and then proceeds downwards, posterior to the carotid artery. At different stages of its course it is joined by other branches of the sympathetic, by a branch from the vagus, and also by filaments from the external laryngeal and recurrent nerves. The *right superior cardiac nerve* is continued into the thorax by passing posterior or anterior to the subclavian artery, and it ends in the deep cardiac plexus. The *left superior cardiac nerve* follows the left common carotid artery in the thorax, and, after crossing the left side of the arch of the aorta, ends in the superficial cardiac plexus.

Ganglion Cervicale Medium.—The middle cervical ganglion is the smallest of the three ganglia of the neck. It is placed opposite the sixth cervical vertebra, in close proximity to the inferior thyreoid artery, upon which it not infrequently rests. Its branches are: (1) *grey rami communicantes*, which pass between the contiguous margins of the scalenus anterior and longus colli muscles and connect the ganglion with the *fifth* and *sixth cervical nerves*; (2) *thyreoid branches*, which run to the thyreoid gland, along the inferior thyreoid artery, and form connections with the external laryngeal and recurrent nerves; (3) the middle cardiac nerve.

On both sides *the middle cardiac nerve* enters the thorax and is lost in the deep cardiac plexus. On the *right side*, it passes posterior or anterior to the subclavian artery; on

the *left side*, it is continued downwards between the common carotid and subclavian arteries.

Ganglion Cervicale Inferius.—The inferior cervical ganglion is lodged in the interval between the transverse process of the seventh cervical vertebra and the neck of the first rib. In that position it lies posterior to the vertebral artery. It is by no means uncommon to find it more or less completely fused, over the neck of the first rib, with the first thoracic ganglion. The connection between it and the middle cervical ganglion is generally in the form of two or more slender nerve cords. One of the cords passes anterior to the subclavian artery, loops round below it and ascends behind it. That loop is termed the *ansa subclavia* (Vieussenii).

The branches of the inferior cervical ganglion are:—

1. Grey rami communicantes to the seventh and eighth cervical nerves.
2. Rami vasculares.
3. Nervus cardiacus inferior.

The *vascular rami* are fine branches which form a plexus around the subclavian artery and its branches. Those around the vertebral artery are remarkable for their large size.

The *inferior cardiac nerve*, on both sides, enters the deep cardiac plexus.

Thyreoid Gland—Trachea—Œsophagus.

After the vessels and nerves of the neck have been studied the dissectors should examine the thyreoid gland, the trachea, and the œsophagus.

Glandula Thyreoidea.—The thyreoid gland is a highly vascular, solid body, which clasps the upper part of the trachea and extends upwards for some distance upon each side of the larynx. It is enclosed in a sheath of the pre-tracheal layer of the cervical fascia, which is attached above to the front and sides of the larynx. It possesses also its own proper fibrous capsule, which is continuous with the stroma of the gland. Between the sheath and the capsule the arteries of supply ramify before they enter the gland substance, and the emerging veins anastomose with one another to form the various thyreoid veins. It varies greatly in size in different subjects; and in females and children it is always relatively larger than in adult males. It consists of

three well-marked subdivisions, viz., two lobes joined across the median plane by the isthmus. Each *lobe* is somewhat conical in form; its base lies at the level of the fifth or the sixth tracheal ring, whilst its apex rests against the side of the thyreoid cartilage. Its *superficial* or *lateral surface* is full

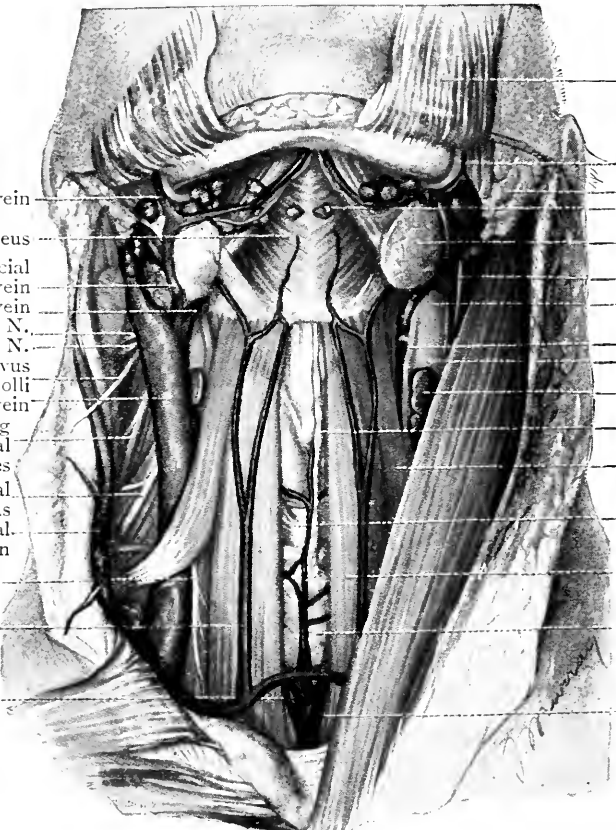

FIG. 82.—Dissection of the Anterior Part of the Neck. The Right Sterno-mastoid has been removed.

and rounded; it is covered superficially by the sterno-thyreoid, sterno-hyoid, and omo-hyoid muscles, and is overlapped by the anterior border of the sterno-mastoid (Fig. 83, p. 230). Its *deep* or *medial surface* is adapted to the parts upon which it lies, viz., to the side of the trachea, the cricoid cartilage, and the thyreoid cartilage. Its *posterior border* is in relation with the lateral margins of

the œsophagus and the pharynx, and the recurrent nerve. In most cases it overlaps the common carotid artery. Its anterior border is connected with the anterior border of the opposite lobe by the isthmus. Above the isthmus it is in relation with the anterior terminal branch of the superior thyreoid artery, and, below the isthmus, with the commencement of the inferior thyreoid vein.

The *isthmus* of the thyreoid gland has already been seen in the dissection of the middle line of the neck. It is a band of varying width which lies anterior to the second, third, and fourth rings of the trachea, and, therefore, nearer the lower than the upper ends of the two lobes.

An additional lobe, the *pyramidal* or *middle lobe*, is frequently present. It is an elongated slender process which springs from the isthmus, on one or other side of the median plane (more usually on the left side), and extends upwards towards the hyoid bone. It may be connected to the hyoid bone by fibrous tissue, or by a narrow slip of muscular fibres called the *levator glandulæ thyreoideæ.* That little muscle, in some cases, has an attachment to the thyreoid gland independently of the pyramidal process. The thyreoid gland is firmly connected by fascia to the parts upon which it lies, and therefore follows the larynx in all its movements.

The dissector should note the great vascularity of the thyreoid gland. Four large arteries, and occasionally a fifth smaller vessel, convey blood to its substance. At the apex of each lobe a superior thyreoid branch of the external carotid artery divides into three branches which supply the gland; the two *inferior thyreoid branches*, from the thyreocervical trunks of the subclavian arteries, distribute their terminal branches to the basal portions and deep surfaces of the two lobes. The occasional artery is the *thyreoidea ima*, a branch of the innominate or, more rarely, of the common carotid or the aortic arch. It ascends, upon the anterior aspect of the trachea, to reach the isthmus of the thyreoid gland. These thyreoid arteries anastomose with one another.

The veins which drain the blood away from the thyreoid gland are still more numerous. They arise, in part, by tributaries which spring from a venous network on the anterior surface of the gland, but chiefly by branches which emerge from its substance. They are *three* in number on

each side—viz., the superior thyreoid, the middle thyreoid, and the inferior thyreoid. The *superior and middle thyreoid veins* cross the common carotid artery and join the internal jugular; the *inferior thyreoid vein* descends on the trachea. At the root of the neck it usually joins its fellow of the opposite side to form a common stem which opens into the left innominate, in the thorax.

Trachea and Œsophagus.—The cervical portions of the windpipe and the gullet may now be studied. Both the trachea and the œsophagus begin at the level of the cricoid cartilage, anterior to the sixth cervical vertebra. From that

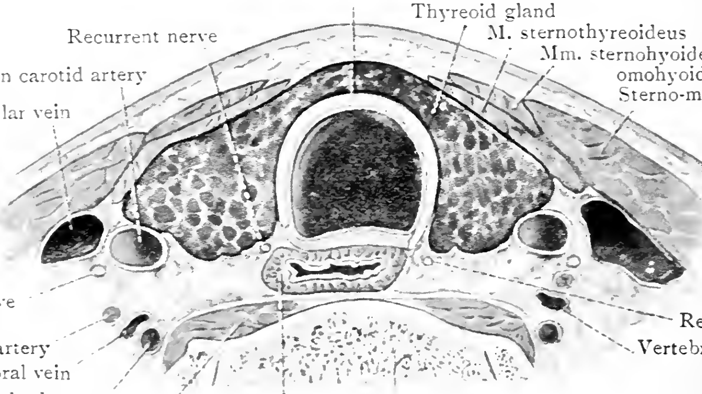

FIG. 83.—Transverse section through the Thyreoid Gland, Trachea, and Gullet, at the level of the first Thoracic Vertebra.

point they extend downwards, anterior to the vertebral column, to the thoracic cavity.

The *trachea*, or *windpipe*, is a wide tube which is kept constantly patent by the cartilaginous curved bars embedded in its walls. The bars do not form complete circles; posteriorly they are deficient, and, in consequence, the posterior surface of the trachea is flattened. The trachea is continuous above with the larynx, and, throughout its course in the neck, it is placed in the median plane of the body. The *anterior* relations of the trachea have already been fully discussed in the account of the parts which occupy the middle line of the neck (p. 127). *Posteriorly*, it rests upon the gullet. A common carotid artery and the corresponding

lobe of the thyreoid gland lie upon each side of it, the lobe of the gland being closely applied to its upper part. A recurrent nerve ascends, on each side, in the angle between the trachea and œsophagus.

The *œsophagus* or *gullet* is a narrow tube, with thick muscular walls, which extends from the pharynx to the stomach. In the cervical part of its course it lies between the trachea and the longus colli muscles, and as it descends it inclines slightly to the left, so that it comes more closely into relation with the lobe of the thyreoid gland and the carotid sheath upon the left side than with the same structures on the opposite side (Figs. 54, 83, 108, 109).

The dissector may terminate his dissection of the neck by an examination of the scalene muscles and the rectus capitis lateralis muscle.

Scalene Muscles and Rectus Lateralis.

Musculi Scaleni.—The scalene muscles constitute the fleshy mass which is seen extending from the transverse processes of the cervical vertebræ to the upper two costal arches. They are three in number, and are named, from their relative positions, *anterior*, *medius*, and *posterior*.

Musculus Scalenus Anterior.—The scalenus anterior is a well-defined muscle which is separated from the scalenus medius by the roots of the brachial plexus and the subclavian artery. It arises from the anterior tubercles of the transverse processes of the third, fourth, fifth and sixth cervical vertebræ, and, tapering somewhat as it descends, it is inserted into the scalene tubercle on the inner margin of the first rib, and also into the superior surface of the same bone between the grooves for the subclavian artery and vein (Fig. 84).

The upper part of its *anterior surface* is concealed by the sterno-mastoid, and the lower part by the clavicle. The common carotid artery ascends along its medial border. Between it and the sterno-mastoid lie—(1) the internal jugular vein; (2) the intermediate tendon of the omo-hyoid; (3) the phrenic nerve, passing downwards and forwards; and (4) the transverse cervical and transverse scapular arteries, passing backwards and laterally, superficial to the phrenic nerve. Between it and the clavicle lies the subclavian vein.

Its *posterior surface* is in relation, above, with the tips of

the lower cervical transverse processes, and below, with the apex of the pleura, the second part of the subclavian artery, and its costo-cervical branch. The *lateral border* touches the roots of the brachial plexus, and the *medial border* is in relation with the thyreo-cervical artery, its inferior thyreoid branch, and with the vertebral artery (Fig. 54).

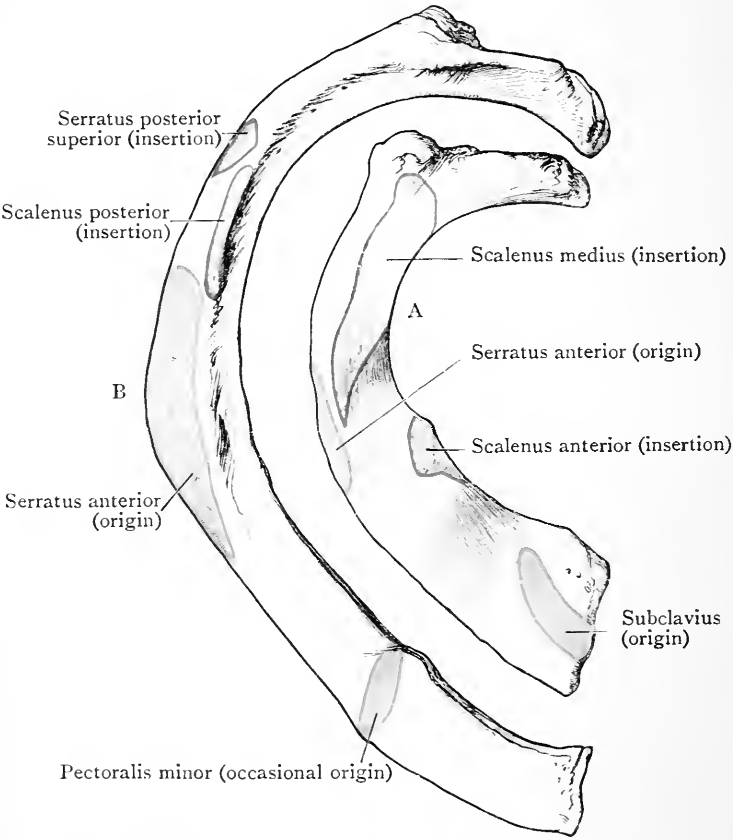

FIG. 84.—Muscle-Attachments to the Superior Surface of the First Rib, and the Outer Surface of the Second Rib.

A, First rib; B, Second rib.

Musculus Scalenus Medius.—The scalenus medius is a more powerful muscle than the scalenus anterior. It springs from the posterior tubercles of all the cervical transverse processes (with the exception, in some cases, of the first), and it is inserted into a rough oval impression which marks the upper surface of the first rib, between the tubercle of the rib and the groove for the subclavian artery (Fig. 84).

It forms part of the floor of the posterior triangle of the neck. Its superficial surface is in relation with the brachial plexus and the third part of the subclavian artery. Its posterior border touches the levator scapulæ; and the dorsal scapular nerve and the descending branch of the transverse cervical artery pass between it and that muscle. The lower part of its anterior border is in relation with the apex of the pleura, and the upper two roots of the long thoracic nerve pierce the substance of the muscle.

Musculus Scalenus Posterior. — The scalenus posterior is generally inseparable, at its origin, from the scalenus medius. It is the smallest of the three, and springs by two or three slips from the transverse processes of a corresponding number of the lower cervical vertebræ, in common with the scalenus medius. It is inserted into the upper border of the second rib, immediately anterior to the insertion of the levator costæ and behind the large rough area which marks the origin of the serratus anterior (Fig. 84).

The scalene muscles are supplied by twigs from the *anterior branches of the cervical nerves, particularly the lower four.* They elevated the ribs to which they are attached and are, therefore, muscles of thoracic respiration.

Dissection.—The little muscle termed the rectus capitis lateralis should now be cleaned, and its attachments defined. It lies in the interval between the transverse process of the atlas and the jugular process of the occipital bone, posterior to the commencement of the internal jugular vein. The anterior ramus of the first cervical nerve will be seen emerging from under cover of its medial margin.

Rectus Capitis Lateralis.—The rectus lateralis arises from the anterior part of the upper surface of the extremity of the transverse process of the atlas, and is inserted into the under surface of the jugular process of the occipital bone. It is supplied by a twig from the *anterior ramus of the first cervical nerve.*

Dissection.—By the time that the dissectors of the head and neck have arrived at this stage of their work, the dissectors of the thorax have, in all probability, finished their dissection. If that is the case, the head and neck may be removed from the trunk by cutting through the vertebral column at the level of the intervertebral fibro-cartilage between the third and fourth thoracic vertebræ. By this proceeding the upper three thoracic vertebræ, with the attached portions of the first, second, and third pairs of ribs, are removed with the neck. The scalene muscles and the longus colli are therefore preserved intact.

THE LATERAL PART OF THE MIDDLE CRANIAL FOSSA.

The structures contained within the middle cranial fossa may now be examined or re-examined. In carrying out this dissection, the head should be supported on a block so that the floor of the cranial cavity looks upwards. The following are the structures which must be displayed :—

1. Cavernous venous sinus.
2. Internal carotid artery.
3. Middle meningeal artery.
4. Accessory meningeal artery.
5. The two roots of the Trigeminal nerve, with the Semilunar ganglion and the three main divisions of the trigeminal nerve.
6. Oculo-motor nerve (3rd cerebral).
7. Trochlear nerve (4th cerebral).
8. Abducent nerve (6th cerebral).
9. Internal carotid plexus of the sympathetic.
10. Greater superficial petrosal nerve.
11. Lesser superficial petrosal nerve.

Dissection.—The dura mater has already been removed from one half of the middle cranial fossa (pp. 109, 110), and on that side it is necessary only to differentiate again the structures which lie in the cavernous sinus; on the other side the dura mater must be stripped from the medial part of the lateral portion of the middle cranial fossa. Enter the knife at the anterior clinoid process, and carry it backwards to the apex of the petrous bone. This incision must go no deeper than is necessary to divide the dura mater, and must be made immediately to the lateral side of the openings in the membrane through which the oculo-motor, the trochlear, and trigeminal nerves pass. It is very important to preserve those apertures intact, so that the proximal ends of the nerves may be held in position during the dissection. The incision through the dura mater may now be carried backwards and laterally along the upper border of the petrous bone in the line of the superior petrosal sinus, and, forwards and laterally, along the posterior margin of the small wing of the sphenoid. After the incisions are made, raise the dura mater with great care, for it is intimately connected with the nerves which lie subjacent to it. Thus, where it forms the lateral wall of the cavernous sinus, it is closely applied to the oculo-motor and trochlear nerves, and it is firmly attached to the ophthalmic division of the trigeminal nerve, whilst over the petrous bone it is united to the surface of the semilunar ganglion, and the greater and lesser superficial petrosal nerves are immediately beneath it. The edge of the knife, therefore, must be kept close to the membrane, and a small portion of the membrane may be left upon the nerves. The part which is left can be removed afterwards as the nerves are defined.

Sinus Cavernosus.—The cavernous sinus has been opened by the above dissection. It is a short, wide venous channel, which extends, along the side of the body of the sphenoid bone, from the lower and medial end of the superior orbital fissure (O.T. sphenoidal fissure) to the apex of the petrous portion of the temporal bone. Anteriorly, blood is conducted into it by the ophthalmic veins and the spheno-parietal sinus; whilst posteriorly, the blood is drained away by the superior and inferior petrosal sinuses. But it has still other connections. Thus, it receives blood from the lower part of the lateral surface of the brain by the superficial middle cerebral vein and some small inferior cerebral veins. It is united with the corresponding sinus of the opposite side by means of the

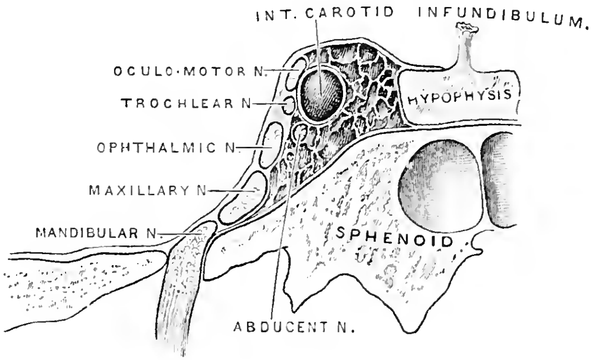

FIG. 85.—Section through the Cavernous Sinus. (After Merkel, somewhat modified.)

anterior and posterior intercavernous sinuses (p. 107). Lastly, one or more emissary veins leave its lower aspect; one passes out of the cranium by the foramen ovale, or it may be through the foramen Vesalii, and ends in the pterygoid venous plexus; and others accompany the internal carotid artery, through the foramen lacerum and the carotid canal, and end in the pharyngeal plexus.

The cavernous sinus is formed in the same manner as the other venous sinuses. The two layers of the dura mater are separated from each other, and the interval is lined with a delicate membrane. An intricate network of interlacing trabeculæ occupies the lumen of the channel, and it is on that account that the term "cavernous" is applied to the sinus. The cavernous sinus has a special importance on account of its being traversed by—the internal carotid artery;

the internal carotid plexus; the oculo-motor, trochlear, and abducent nerves; and the ophthalmic division of the trigeminal nerve. The precise relations which those structures bear to its walls will be described later; in the meantime it is necessary only to note that two, viz., the internal carotid artery and the abducent nerve, lie more distinctly within the interval between the two layers of the dura mater than the others, but that they are shut out from the blood channel by the delicate lining membrane of the sinus. The oculo-motor and trochlear nerves, and the ophthalmic division of the

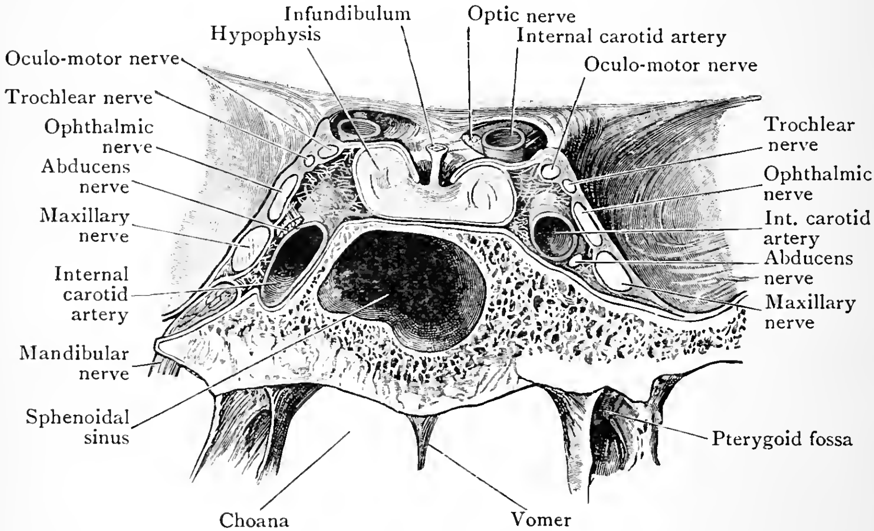

FIG. 86.—Frontal section through the Cavernous Sinus to show the position of the Nerves in its wall. Note the branch given to the hypophysis (O.T. pituitary body) by the internal carotid artery.

trigeminal nerve, are closely applied to the lateral wall of the sinus (Figs. 85, 86, 87, 92).

Nervus Trigeminus.—The two roots of the trigeminal nerve have already been seen passing between the two layers of the dura mater, at the apex of the petrous portion of the temporal bone, under the anterior margin of the tentorium. Now that the dura mater has been raised from the lateral part of the middle cranial fossa, the further relations of those nerve-roots within the cranium may be studied. It will be noticed that the loosely connected and parallel funiculi of the *portio major*, or sensory root, at once begin to divide and join with each other so as to form a dense plexiform

arrangement, whilst, at the same time, the nerve-root increases somewhat in breadth. The interlacement, thus brought about, occupies the smooth depression which marks the anterior aspect of the apex of the petrous portion of the temporal bone, and it sinks into the semilunar ganglion (O.T. Gasserian).

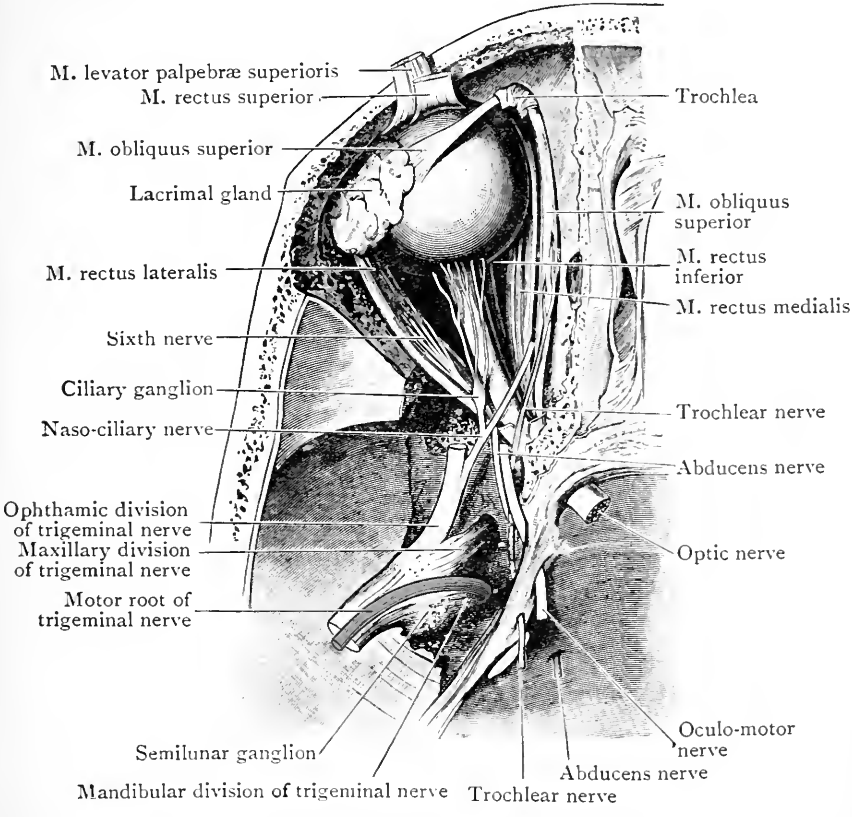

FIG. 87.—Dissection of the Orbit and the Middle Cranial Fossa. Both roots of the fifth nerve, with the semilunar ganglion, are turned laterally.

The *Semilunar Ganglion* (O.T. Gasserian) is somewhat crescentic in form. It lies upon the sutural junction between the apex of the petrous bone and the great wing of the sphenoid bone. There it is enclosed within a recess or space, called the *cavum Meckelii*, formed by a separation of the two layers of the dura mater. The concavity of the ganglion is directed postero-medially, and it is upon that aspect that it receives the interlacing fibres of the sensory root of the trigeminal nerve; the convexity of the ganglion is directed

antero-laterally and from it emerge the three main divisions of the trigeminal nerve. They are—(1) the first, or ophthalmic division; (2) the second, or maxillary division; and (3) the third, or mandibular division. The medial border of the ganglion is connected with the internal carotid sympathetic plexus by filaments of communication.

The *portio minor*, or motor root, of the fifth nerve should now be followed. Before the nerve passes into Meckel's cave the motor root lies along the medial side of the large sensory root, but it soon changes its position and then lies beneath the sensory part. To display that relationship, draw the cut ends of the two roots through the aperture in the dura mater which leads into Meckel's cave, and, gently dislodging the semilunar ganglion from its place, turn it forwards and laterally so as to expose its deep surface. The small and firm motor root can readily be recognised lying in a groove on the deep surface of the ganglion; if it is displaced from the groove, it will be seen to have no connection with the ganglion, but to be continued onwards towards the foramen ovale. It ultimately joins the mandibular division of the trigeminal nerve. The junction may take place within the cranium, in the foramen ovale, or immediately outside the skull.

Dissection.—The three principal divisions of the trigeminal nerve may next be examined. Begin with the *mandibular division*, which is the largest. It proceeds directly downwards, and almost immediately leaves the cranial cavity through the foramen ovale.

Whilst isolating the mandibular division and defining the bony aperture through which it makes its exit, look carefully for the accessory meningeal artery, which enters the cranium through the same foramen. If the injection has been forced into the vessel it can easily be detected. An emissary vein which connects the cavernous sinus with the pterygoid venous plexus also passes through the foramen ovale.

The *maxillary division* is composed entirely of sensory fibres. It runs forwards, in relation to the lower and lateral part of the cavernous sinus, and, after a short course within the cranium, makes its exit through the foramen rotundum. Near its origin it gives off a fine *meningeal branch* to the dura mater of the middle fossa of the cranium.

The *ophthalmic division* is the smallest of the three branches of the trigeminal nerve, and, like the maxillary, it is composed entirely of sensory fibres. It passes forwards, in the

lateral wall of the cavernous sinus, and ends, close to the superior orbital fissure, by dividing into three terminal branches. As it traverses the sinus it is accompanied by the oculomotor and trochlear nerves, both of which occupy a higher level. Like the other two divisions of the trigeminal nerve, the ophthalmic nerve gives off a *meningeal branch*; it is a small twig which passes into the tentorium cerebelli.

The terminal branches of the ophthalmic division of the trigeminal nerve are the naso-ciliary, the lacrimal, and the frontal. The *naso-ciliary*, as a rule, takes origin first; the *lacrimal* is given off soon after; and then the stem of the nerve is continued onwards as the *frontal*. The three branches enter the orbit through the superior orbital fissure.

Nervus Oculomotorius (Third), et Nervus Trochlearis (Fourth), et Nervus Abducens (Sixth).—It has been noted already that the *oculo-motor* nerve pierces the dura mater within the small triangular area, in the middle cranial fossa, which lies immediately anterior to the crossing of the attached and free margins of the tentorium (p. 108). It has been noted also that the *trochlear* (fourth) nerve pierces the dura mater in the posterior fossa under the free margin of the tentorium. Both proceed forwards in the lateral wall of the cavernous sinus. The oculo-motor nerve occupies the highest level, then comes the trochlear nerve, and immediately below that the ophthalmic division of the trigeminal nerve. The three nerves, therefore, present a numerical order from above downwards. The *abducent nerve*, which pierces the dura mater in the posterior fossa, at the lower and lateral part of the dorsum sellæ, curves round the lateral side of the internal carotid artery, and then passes forwards more directly within the cavernous sinus than the others (Fig. 85).

The oculo-motor, trochlear, and abducent nerves, during their course in the cavernous sinus, receive communications from the carotid plexus and from the ophthalmic nerve; and they all enter the orbit by passing through the superior orbital fissure. Before doing so, the oculomotor nerve divides into an upper and a lower division. As they pass through the superior orbital fissure the various nerves undergo a change in their relative positions. That, however, will be studied in the dissection of the orbit.

Arteria Carotis Interna.—The intracranial portion of the internal carotid artery may now be examined (Figs. 39, 85,

86, 92). It lies upon the lateral aspect of the body of the sphenoid, and, for the greater part of its course, it traverses the cavernous sinus. It emerges from the carotid canal into the foramen lacerum at the apex of the petrous bone ; then it passes through the upper part of the foramen lacerum, pierces the outer layer of dura mater, and enters the middle cranial fossa, at the

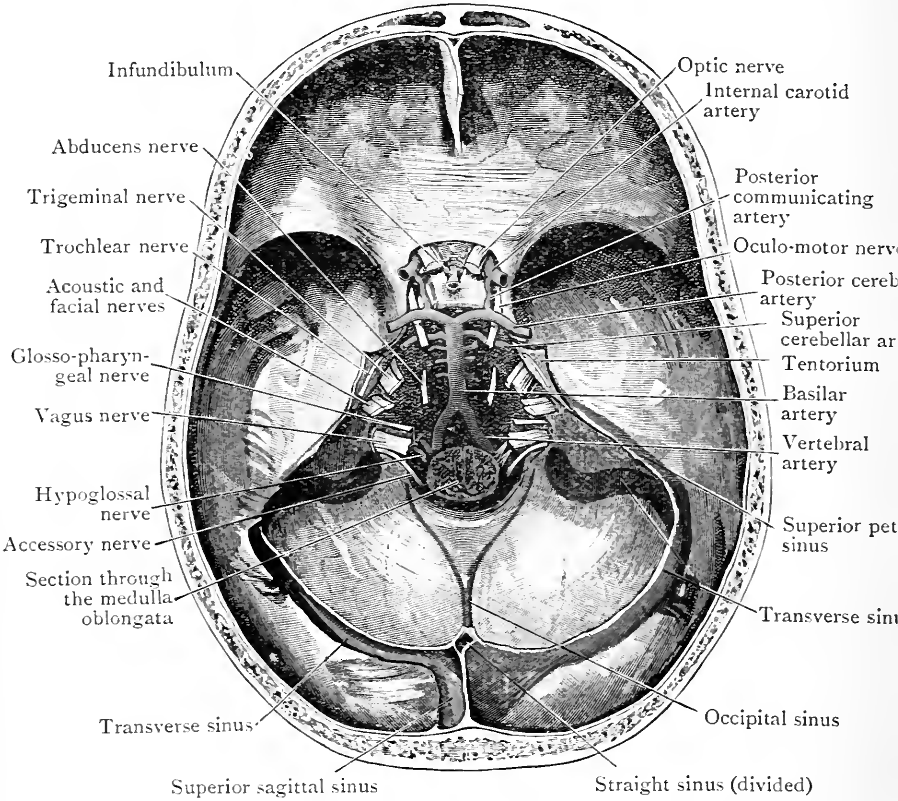

FIG. 88.—Floor of the Cranium after the removal of the Brain and the Tentorium Cerebelli. The blood vessels forming the circulus arteriosus have been left in place.

root of the posterior clinoid process ; there it bends, at right angles, and passes forwards to the lower root of the small wing of the sphenoid, where it turns abruptly upwards and pierces the inner layer of the dura mater, immediately posterior to the entrance of the optic nerve into the optic foramen and on the medial side of the anterior clinoid process. It was severed at that point during the removal of the brain ; but it will be afterwards seen to end, on the basal aspect of the

brain, at the commencement of the lateral fissure (O.T. Sylvian fissure), by dividing into the anterior and middle cerebral arteries. Throughout its whole course it is surrounded by sympathetic filaments, and soon after its entrance into the cranium the abducent nerve crosses its lateral side.

The intracranial portion of the internal carotid artery gives off the following branches:—

1. Branches to the hypophysis, 2. Branches to the semilunar ganglion, 3. Branches to the dura mater,	These are minute twigs which arise in the cavernous sinus.
4. Ophthalmic, 5. Posterior communicating, 6. Anterior cerebral, } terminal 7. Middle cerebral, } branches. 8. Chorioidal.	These will be studied at a later stage.

Plexus Caroticus Internus.—The sympathetic filaments which form the internal carotid plexus can be satisfactorily dissected only in a subject which has not been injected; and even then, the dissection is an exceedingly difficult one. The *internal carotid plexus* is placed in the cavernous sinus and is massed chiefly upon the lower and medial aspect of the internal carotid artery, at the point where it makes its bend upwards. It supplies filaments to the hypophysis, to the third and fourth nerves, to the ophthalmic division of the trigeminal nerve and to the semilunar ganglion, and gives the sympathetic root to the ciliary ganglion (O.T. lenticular ganglion).

Nervus Petrosus Superficialis Major.—The greater superficial petrosal nerve, along with a small arterial twig from the middle meningeal artery, can readily be exposed in the groove, on the anterior face of the petrous bone, which leads from the hiatus canalis facialis to the foramen lacerum. It is placed under the semilunar ganglion, which must therefore be turned forwards and laterally. In the canalis facialis it joins the ganglion geniculi of the facial nerve. When traced in the opposite direction, it will be found to enter the foramen lacerum, where it joins the *deep petrosal nerve* from the carotid plexus. The trunk formed by the union of these two filaments is the *nerve of the pterygoid canal* (O.T. *Vidian nerve*).

Nervus Petrosus Superficialis Minor.—The lesser superficial petrosal nerve appears upon the anterior face of the petrous bone, through an aperture which is placed immediately lateral to the hiatus canalis facialis. It leaves the cranial cavity by passing downwards between the great wing of the sphenoid and the petrous part of the temporal bone, or through the canaliculus innominatus or through the foramen ovale, to reach the otic

ganglion. It, as has been mentioned already (p. 220), is formed by the union of the tympanic branch of the glosso-pharyngeal with a branch from the ganglion geniculi of the facial.

External Superficial Petrosal Nerve.—It is convenient at this stage to take note of a fourth petrosal nerve—*the external superficial petrosal.* It takes origin from the sympathetic plexus which accompanies the middle meningeal artery, and, entering the petrous bone, is conducted to the ganglion geniculi of the facial nerve.

Middle and Accessory Meningeal Arteries.—The entrance of the *middle meningeal artery* through the foramen spinosum should now be examined. It gives minute twigs to the semilunar ganglion, and one—*the superficial petrosal artery*—which accompanies the greater superficial petrosal nerve into the hiatus canalis facialis. The further course of the middle meningeal artery has been described already (p. 118). The nervus spinosus, from the mandibular nerve, also enters the cranium through the foramen spinosum (p. 179).

The *accessory meningeal artery* enters the cranium through the foramen ovale, and is distributed chiefly to the semilunar ganglion.

THE ORBIT.

Within the orbital cavity the following structures are grouped around the eyeball and the optic nerve :—

Muscles, . .	Rectus superior. Rectus inferior. Rectus lateralis. Rectus medialis. Obliquus superior. Obliquus inferior. Levator palpebræ superioris.
Vessels, . .	Ophthalmic artery and its branches. Ophthalmic veins (superior and inferior), with their tributaries.
Nerves, . .	Oculo-motor (3rd cerebral). Trochlear (4th cerebral). Abducent (6th cerebral). Frontal, Lacrimal, Naso-ciliary, from ophthalmic division of the trigeminal or fifth cerebral nerve. Zygomatic branch of the maxillary division of the trigeminal nerve.
	Ciliary ganglion. Lacrimal gland. Fascia Bulbi.

Dissection.—The roof of the orbit must be removed with the aid of the saw, the chisel, and the bone forceps. Begin by

PLATE VIII

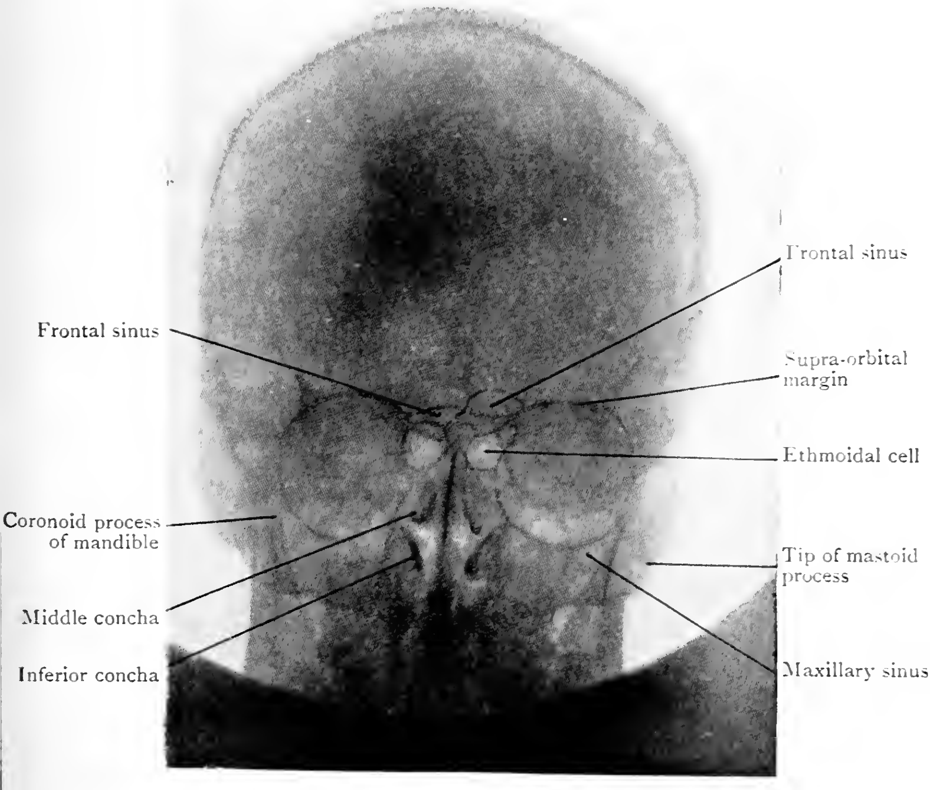

FIG. 89.—Antero-posterior radiograph of Living Skull. (Gouldesbrough.)

PLATE IX

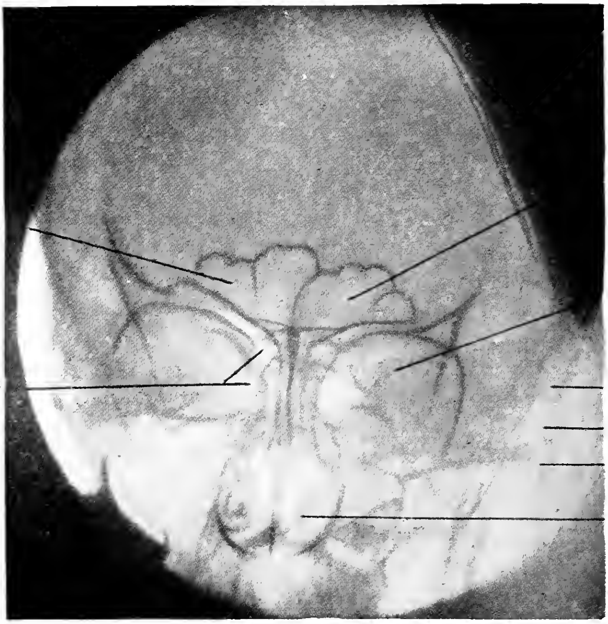

FIG. 90.—Antero-posterior radiograph of Skull, showing large frontal sinuses.

removing the thick cranial wall above the orbital opening, leaving only a thin portion corresponding to the superior orbital arch.

Strip the soft structures including the periosteum downwards from the cut margin of the skull to the superior orbital margin. Then take the saw and make two incisions through the frontal bone to the floor of the anterior fossa. One, vertically downwards, opposite the anterior end of the cribriform plate of the ethmoid, and the second downwards and forwards immediately anterior to the lateral end of the small wing of the sphenoid. After the saw cuts are made take the bone forceps and chip away the frontal bone between the saw cuts, to the level of the floor of the anterior fossa. As the bone is removed the frontal air sinus may be opened and its extent should be noted (Figs. 89, 90). Next take the chisel and cut through the floor of the anterior fossa immediately in front of the posterior border of the small wing of the sphenoid. Carry the cut medially to 2 mm. in front of the optic foramen; then turn it forwards along the medial border of the orbital plate of the frontal bone and lateral to the depression in the region of the cribriform plate of the ethmoid; then, with the aid of the chisel and bone forceps, gradually chip away the whole of the bony roof of the orbit, but do not injure the subjacent periosteum. Next remove the remains of the small wing of the sphenoid with the exception of the margin of the optic foramen, which must be left intact. The superior orbital fissure is now fully opened up, and no difficulty will be met with as the nerves in the wall of the cavernous sinus are traced forwards into the orbit, but the anterior clinoid process may be chipped away to gain additional freedom for further dissection. After the bony roof of the orbit has been removed examine the exposed periosteum.

Periosteum. — If the dissection has been successfully carried out, the periosteum clothing the under surface of the orbital roof will be exposed uninjured. The periosteum of the orbit forms a funnel-shaped sheath, which encloses all the contents of the cavity except the zygomatic and infra-orbital nerves and the infra-orbital artery. It is but loosely attached to its bony walls. Posteriorly, it is directly continuous, through the superior orbital fissure, with the dura mater. Expanding with the cavity, it becomes continuous anteriorly, around the orbital opening, with the periosteum which clothes the exterior of the skull. There it presents important connections with the palpebral fascia also.

Dissection.—Open the eyelids and draw the eyeball forwards with the forceps; then, with a fine needle, carry a piece of thread through the ocular conjunctiva, being careful not to penetrate the eyeball, for that would render its subsequent inflation impossible. Finally, stitch the thread to the nose, and the eyeball will be securely held forwards. Turn now to the periosteum of the roof of the orbit, divide it transversely, close

to the anterior margin of the orbit, and then, from before backwards, along the middle line of the orbit. Turn the two flaps so marked out laterally and medially respectively. As the region of the superior orbital fissure is approached be careful not to injure the nerves which pass through the fissure; the one most likely to be injured is the small trochlear nerve which lies near the medial end of the fissure. Secure it at once, and trace it forwards through the fat to the superior oblique muscle which lies along the upper part of the medial wall of the

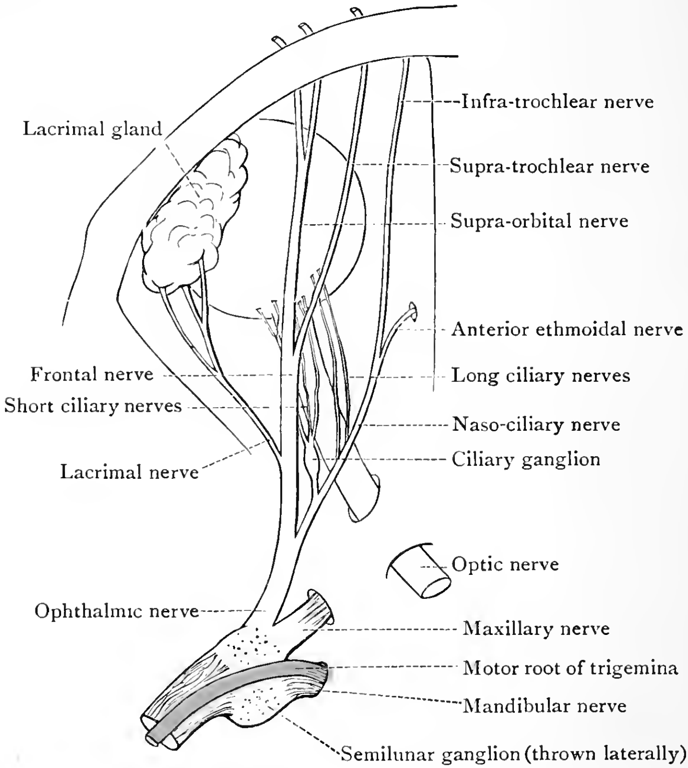

FIG. 91.—The Ophthalmic Nerve of the Left Side. The semilunar ganglion and the nerves have been everted and turned over to show the motor root.

orbit. In the middle line of the orbit the large frontal nerve will be found lying in the fat on the surface of the levator palpebræ superioris. Trace the nerve forwards to its division into its two terminal branches :—a large supra-orbital branch accompanied by a corresponding artery, and a medial and smaller supra-trochlear branch. Follow the supra-trochlear branch to the superior medial angle of the orbit, where it passes above the pulley of the superior oblique muscle. Return to the trochlear nerve and the superior oblique muscle; clean the muscle from behind forwards. It ends in a tendon which passes through the fibrous pulley, situated at the upper and medial angle of the orbit, then turns backwards and laterally. and dis-

appears below the levator palpebræ superioris and the superior rectus. Define both the tendon and the pulley. Return to the frontal nerve, pull it aside and clean the levator palpebræ superioris, upon which the nerve lies. Define the margins of the levator palpebræ and note that it lies upon the superior rectus muscle of the eyeball. Raise the levator palpebræ, carefully, and note a small twig of the superior division of the ocular motor nerve which pierces the superior rectus and enters the levator palpebræ. Now find the lacrimal nerve and the accompanying lacrimal artery, which lie in the fat at the junction of the roof with the lateral wall of the orbit, and trace them forwards to the lacrimal gland. The gland lies under cover of the lateral end of the superior orbital margin. When all the structures which have been mentioned have been found and cleaned study them in detail.

Nervus Frontalis.—The frontal nerve is the continuation of the stem of the ophthalmic division of the trigeminal nerve, after it has given off its lacrimal and naso-ciliary branches. It enters the orbit through the superior orbital fissure, above the muscles, and runs forwards, upon the upper surface of the levator palpebræ superioris, immediately subjacent to the periosteal lining of the orbital cavity. It ends, at a variable distance from the orbital opening, by dividing into the supra-orbital and supra-trochlear branches.

The *supra-trochlear nerve* is the medial and smaller of the two terminal branches of the frontal. It runs towards the trochlea of the superior oblique muscle, above which it pierces the palpebral fascia, leaves the orbit, and turns round the orbital arch to reach the forehead. Its further course has been described already (p. 47). In the orbit it gives off one small twig close to the pulley of the superior oblique muscle; the twig passes downwards to join the infra-trochlear branch of the naso-ciliary nerve.

The *supra-orbital nerve* is continued onwards, in the line of the parent stem, and, passing through the supra-orbital notch or foramen, it turns upwards on the forehead (p. 47). The division of the supra-orbital nerve into a lateral and a medial branch was seen during the dissection of the scalp (p. 47). Sometimes the separation takes place within the orbit, and in that case the larger *lateral* part occupies the supra-orbital notch.

Nervus Lacrimalis.—The lacrimal nerve is the smallest of the terminal branches of the ophthalmic division of the trigeminal. It enters the orbit through the superior orbital fissure, above the level of the muscles, and runs forwards,

PLATE X

PLATE X

FIG. 92.

along the lateral wall of the cavity, above the upper margin of the lateral rectus muscle. At the anterior part of the orbit it continues its course, under cover of the lacrimal gland, until it reaches the lateral part of the upper eyelid, in which it ends (p. 27). Within the orbital cavity it gives numerous twigs to the deep surface of the lacrimal gland, and sends downwards a filament which connects it with the zygomatic branch of the maxillary nerve.

Nervus Trochlearis.—The small trochlear nerve is destined entirely for the supply of the superior oblique muscle. Having entered the orbit through the superior orbital fissure, above the muscles, it passes forwards and medially, under the periosteum, and finally sinks into the posterior part of the upper or orbital surface of the superior oblique muscle.

Glandula Lacrimalis.—The lacrimal gland is a small, flattened and distinctly lobular structure, of oval form, which is placed in the antero-lateral part of the orbit, its long axis lying parallel with the anterior margin of the orbit (Figs. 92, 97). It consists of two parts or groups of lobules—a superior and an inferior—imperfectly separated from each other. The *glandula lacrimalis superior*, which constitutes the main mass of the gland, lies in the orbital cavity. Its lateral convex surface is lodged in a hollow upon the medial aspect of the zygomatic process of the frontal bone, and it is bound to the lateral part of the orbital arch by short fibrous bands which proceed from the periosteum. The deep or medial surface is slightly concave, and rests upon the levator palpebræ superioris and lateral rectus, which intervene between it and the eyeball. The *glandula lacrimalis inferior* lies below and anterior to the superior part, from which it is partially separated by the expanded tendon of the levator palpebræ superioris. It projects into the base of the upper eyelid, and rests upon the conjunctiva which lines the deep aspect of the lid. That portion of the gland has been already examined in the dissection of the eyelids (p. 27). Even in the undissected subject it can be seen, through the conjunctiva, when the upper eyelid is fully everted.

The lacrimal gland secretes the tears, and its ducts (three to five from the superior part and three to nine from the inferior part) open upon the deep surface of the upper eyelid in the neighbourhood of the fornix (Fig. 9).

Musculus Levator Palpebræ Superioris.—The elevator

muscle of the upper eyelid rests upon the upper surface of the rectus superior. Posteriorly, it is narrow and pointed, but it expands as it passes forwards, above the eyeball, to the upper eyelid. It arises from the under surface of the roof of the orbit, immediately anterior to the optic foramen and, therefore, from the inferior surface of the small wing of the sphenoid bone. In the anterior part of the orbital cavity it widens out into a broad membranous expansion, which splits into three lamellæ. The most anterior lamella is attached to the palpebral fascia of the upper eyelid and by it to the upper tarsus. The middle lamella is attached directly to the upper border of the upper tarsus. The posterior lamella is attached to the upper margin of the conjunctiva. The lateral and medial margins of the expansion are fixed to the rim of the orbital opening, in close proximity to the medial palpebral ligament and the lateral palpebræ raphe. By those attachments, excessive action of the muscle upon the upper eyelid is checked. The levator palpebræ superioris is supplied by the upper division of the oculo-motor nerve, and it is the elevator not only of the upper eyelid but also of the upper fornix of the conjunctiva.

Dissection.—Divide the frontal nerve and throw the ends forwards and backwards. The levator palpebræ superioris also may be cut midway between its origin and insertion. When the posterior portion is raised a minute nerve twig will be seen entering its deep or ocular surface ; it is a branch of the superior division of the third or oculo-motor nerve.

The eyeball should now be inflated. That may be done from the front or from behind. If the latter method is selected, gently separate the fat under cover of the superior rectus muscle, and push the ciliary vessels and nerves away from the optic nerve. Next, make a small incision through the sheath of the nerve. Pass a ligature round the nerve, anterior to the opening, and then pass a blowpipe, provided with a stylet, through the incision and along the nerve, into the interior of the eyeball. When the globe of the eye is fully inflated, the ligature may be tightened as the blowpipe is withdrawn. A very much better plan, however, is to inflate the eyeball from the front. For that purpose make an oblique valvular aperture in the sclero-corneal junction, with the point of a sharp narrow-bladed knife. Insert a blowpipe through the aperture, and on its withdrawal, after the inflation of the eyeball, the valvular character of the opening is sufficient to prevent the escape of the air.

Posterior to the eyeball, at the sides of the superior rectus, the dissector will notice a quantity of loose bursal-like tissue. It is the *fascia bulbi* (O.T. *capsule of Tenon*). Seize the upper part of it with the forceps, and remove a small portion with a pair of scissors. An aperture is thus made in the fascia, and the

handle of the knife can be introduced into the space between it and the eyeball. In favourable cases the extent of the fascia can be gauged, and perhaps even the prolongations or sheaths which it gives to the tendons of the ocular muscles may be made out. The description of the fascia bulbi is given on p. 259.

Musculus Rectus Superior.—The superior rectus, which lies under cover of the levator palpebræ superioris, is now fully exposed. It is the thinnest of the recti muscles, and it arises from the upper margin of the optic foramen, passes forwards above the optic nerve, and ends, upon the upper aspect of the eyeball, in a thin, delicate and somewhat expanded tendon, which is inserted into the sclera, about 8 mm. posterior to the sclero-corneal junction. It is supplied by a branch from the *superior division* of the *oculomotor nerve*; when it contracts it turns the eyeball so that the centre of the cornea moves upwards and medially.

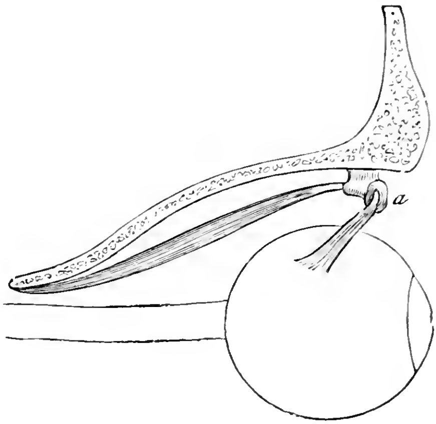

FIG. 93.—Diagram of the Superior Oblique Muscle. (From Hermann Meyer.)

a. Trochlea and synovial sheath.

Musculus Obliquus Superior.—The superior oblique muscle is the longest and narrowest of the muscles attached to the eyeball. It arises from the roof of the orbit, immediately anterior to the upper and medial part of the optic foramen between the rectus superior and the rectus medialis. It passes forwards along the upper part of the medial wall of the cavity, above the medial rectus. At the anterior part of the orbit it ends in a slender tendon, which enters the *trochlea* and at once changes its direction, proceeding backwards and laterally, upon the upper surface of the eyeball, under cover of the superior rectus. Beyond the lateral edge of the superior rectus the tendon expands somewhat, and is inserted into the sclera, midway between the entrance of the optic nerve and the cornea (Fig. 93).

The *trochlea* or *pulley* through which the tendon passes is a small fibro-cartilaginous ring, which is attached by fibrous tissue to the trochlear fossa of the frontal bone. The pulley

is lined with a synovial sheath which facilitates the movement of the tendon; and from its lateral margin it gives a fibrous investment to the tendon.

The superior oblique is supplied by the trochlear nerve and moves the eyeball so that the centre of the cornea is turned downwards and laterally.

> ***Dissection.***—Divide the superior rectus midway between its origin and its insertion, and reflect the cut ends. When the posterior part of the muscle is raised, the superior division of the oculo-motor nerve is brought into view, as it sinks into the deep or ocular surface of the muscle. It sends a twig to the levator palpebræ superioris. The removal of some fat will bring the optic nerve more fully into view. At the posterior part of the orbit three structures will be seen crossing the optic nerve—viz., (1) the naso-ciliary nerve; (2) the ophthalmic artery; and (3) the superior ophthalmic vein. All three must be carefully cleaned and their branches followed out. From the naso-ciliary nerve one or two delicate thread-like branches—the *long ciliary nerves*—will be found passing along the optic nerve to reach the eyeball. The *short ciliary nerves*, much more numerous, accompany the long ciliary branches, and can readily be disengaged from the fat which surrounds the optic nerve. A strong member of the short ciliary group should be selected and followed backwards; it will lead the dissector to the *ciliary ganglion*. That is a minute body which is situated upon the lateral side of the optic nerve in the posterior part of the orbit. With a little patience and care the roots which the naso-ciliary nerve and inferior division of the oculo-motor nerve give to the ciliary ganglion can be isolated, and perhaps even the sympathetic root from the internal carotid plexus will be found. After the ciliary ganglion and its roots and branches have been defined, clear away the fat which lies lateral to the ganglion, and secure the abducens nerve, which enters the ocular surface of the lateral rectus. Then clean the optic nerve (Fig. 92).

Nervus Opticus.—The optic nerve enters the orbit through the optic foramen. It carries with it a strong, loose sheath of dura mater, and also more delicate investments from the arachnoid and pia mater. The ophthalmic artery, which accompanies it, lies on its infero-lateral aspect. Within the orbit the nerve inclines forwards and laterally, and at the same time somewhat downwards, to the back of the eyeball, where it pierces the sclera a short distance to the medial side of the centre of its posterior surface. The dissector has noted already that the ophthalmic artery and vein and the naso-ciliary nerve cross above the optic nerve, and that it is closely accompanied by the delicate ciliary nerves and vessels. The optic nerve is slightly longer than the distance

which it has to run from the optic foramen to the globe of the eye, so that the movements of the eyeball may not be interfered with. Within the eyeball the optic nerve spreads out in the retina.

Nervus Naso-ciliaris.—The naso-ciliary nerve (O.T. nasal) arises from the ophthalmic division of the trigeminal in the anterior part of the cavernous sinus. It passes through the superior orbital fissure and enters the orbital cavity, between the two heads of the lateral rectus muscle and between the two divisions of the third nerve. It then runs forwards and medially, and, crossing obliquely above the optic nerve, it runs between the medial rectus and superior oblique muscles to the medial wall of the orbit, where it divides into two terminal branches — viz., the infra-trochlear and the anterior ethmoidal nerves. In addition to those, it gives off in the orbit the following branches: (1) long root to the ciliary ganglion; (2) long ciliary nerves; (3) posterior ethmoidal nerve.

Radix Longa Ganglii Ciliaris.—The long root of the ciliary ganglion is a very slender filament which springs from the naso-ciliary as it enters the orbit between the heads of the lateral rectus. It runs along the lateral side of the optic nerve, and enters the upper and posterior part of the ciliary ganglion.

Nervi Ciliares Longi.—The two long ciliary branches spring from the naso-ciliary as it crosses the optic nerve. They pass forwards, upon the medial side of the optic nerve, to reach the globe of the eye, where they pierce the sclera. One of the long ciliary nerves very constantly unites with one of the short ciliary filaments.

Nervus Ethmoidalis Posterior.—The posterior ethmoidal nerve passes through the posterior ethmoidal foramen to the ethmoidal cells and the sphenoidal air sinus.

Nervus Infratrochlearis.—The infra-trochlear branch runs along the medial wall of the orbit below the superior oblique muscle. After passing under the trochlea of that muscle, it emerges from the orbit and appears upon the face above the medial commissure of the eyelids, where it has been dissected already (p. 27). Near the pulley it receives a communicating twig from the supra-trochlear nerve.

Nervus Ethmoidalis Anterior.—The anterior ethmoidal nerve is the larger of the two terminal branches of the naso-

ciliary nerve. It leaves the orbit by the anterior ethmoidal canal, and is conducted to the interior of the cranium, in which it appears at the lateral margin of the cribriform plate of the ethmoid. The canal in which it runs can readily be opened up with the bone-forceps to expose the nerve. Upon the cribriform plate it turns forwards, under the dura mater, and almost immediately disappears, through a slit-like aperture at the side of the crista galli, into the nasal cavity. There it gives *internal nasal branches* to the mucous membrane, and is continued downwards upon the posterior aspect of the nasal bone. Finally, it emerges upon the face, as the *external nasal nerve*, by passing between the lower margin of the nasal bone and the lateral cartilage of the nose. Its terminal filaments have been described already (p. 30).

Ganglion Ciliare (Fig. 97).—The ciliary ganglion is a small quadrangular body, not much larger than the head of a large pin. It is placed in the posterior part of the orbit, between the optic nerve and the lateral rectus muscle, and very commonly on the lateral side of the ophthalmic artery. At its posterior border it receives its three roots; whilst from its anterior border the short ciliary nerves are given off.

The *sensory root* is given off by the naso-ciliary, and is called the *long root.* The *short* or *motor root* is a short, stout trunk; it springs from the branch of the oculo-motor nerve which goes to the inferior oblique muscle. The *sympathetic root* is derived from the internal carotid plexus; it joins the ganglion, close to the entrance of the long root from the naso-ciliary nerve. In some cases it joins the long root before it reaches the ganglion.

Nervi Ciliares Breves.—The short ciliary nerves are from five to seven in number. As they pass along the optic nerve they divide and thus increase in number; at the back of the eyeball from twelve to eighteen may be counted. They form two groups, superior and inferior, and the lower nerves are generally more numerous than the upper. Finally, they pierce the sclera by a series of apertures which are placed around the entrance of the optic nerve.

Arteria Ophthalmica.—The ophthalmic artery is a branch of the internal carotid. It accompanies the optic nerve into the orbit through the optic foramen. At first it lies below the optic nerve, but soon winds round its lateral side, and, crossing above it, passes forwards along the medial

wall of the orbit, below the superior oblique muscle. At the medial margin of the front of the orbit it ends by dividing into two terminal branches—viz., the frontal and the dorsal nasal (Fig. 95).

The *branches* of the ophthalmic artery are very numerous, but it is seldom that they can all be satisfactorily displayed, unless a special injection has been made. They are :—

1. Lacrimal.	4. Ciliary.	7. Palpebral.
2. Muscular.	5. Supra-orbital.	8. Dorsal nasal.
3. Arteria centralis retinæ.	6. Ethmoidal.	9. Frontal.

Arteria Lacrimalis.—The lacrimal branch accompanies the lacrimal nerve; it supplies the lacrimal gland and the

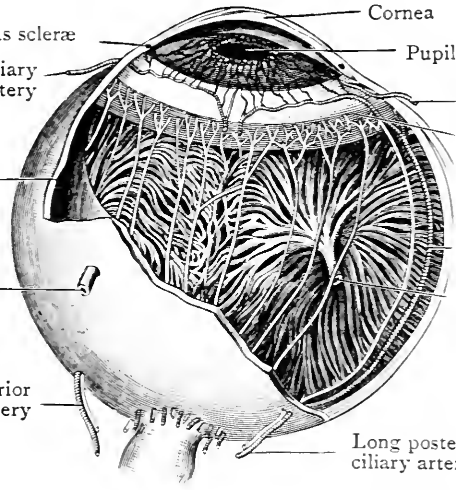

FIG. 94.—Dissection of the Eyeball showing the Arrangement of the Ciliary Nerves and Vessels.

conjunctiva. In each eyelid an arterial arch, the *arcus tarseus*, is formed by the anastomoses of the two lateral palpebral branches of the lacrimal with the two medial palpebral branches of the ophthalmic.

Muscular branches come off at variable points, not only from the main artery, but also from certain of its branches. They supply the muscles contained in the orbital cavity.

Arteria Centralis Retinæ.—The arteria centralis retinæ is a minute but important artery. It pierces the infero-medial surface of the optic nerve, 12 mm. (about half an inch) posterior to the eyeball, and passes, in the substance of the nerve, to the interior of the globe of the eye.

Arteriæ Ciliares.—The ciliary arteries are very numerous. Two groups are recognised—viz., a posterior and an anterior. Two sets of posterior ciliary arteries are described. They are known as the short and the long posterior ciliary arteries respectively. The *short ciliary arteries* are several in number; they spring partly from the ophthalmic trunk and partly from its lacrimal and muscular branches. They accompany the short ciliary nerves and, after piercing the posterior part of

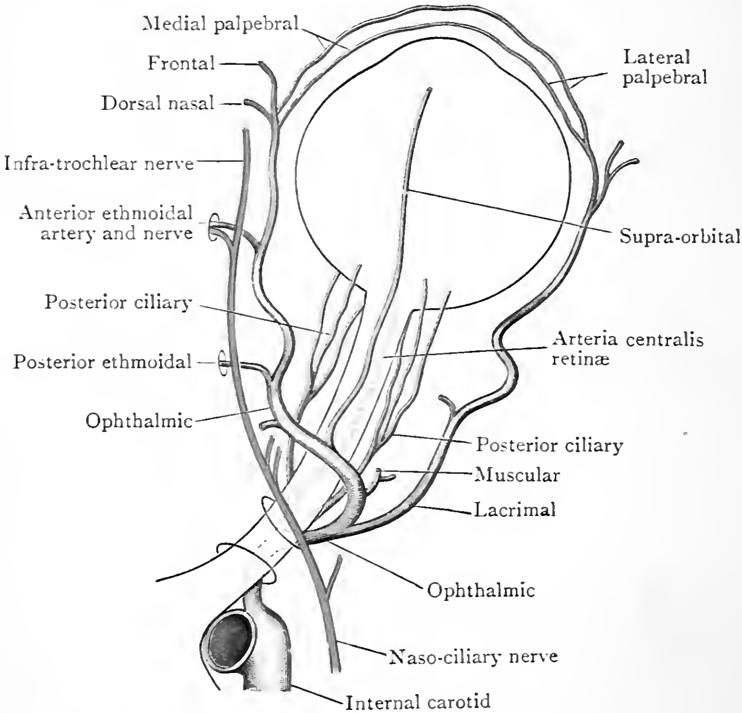

FIG. 95.—Diagram of the Ophthalmic Artery and its Branches. (After Quain and Meyer, modified.)

the sclera, around the optic nerve, they enter the choriocapillary layer of the chorioid. The *long posterior ciliary arteries* (Fig. 94) are two in number. They spring from the ophthalmic trunk and run forwards, one on each side of the optic nerve. After they have pierced the sclera they run forward, one on each side, in the horizontal plane, and between the sclera and the chorioid to the iris. The *anterior ciliary arteries* come off, in the anterior part of the orbit, from the lacrimal and muscular branches. They vary in number from six to eight, and run to the anterior part of

the eyeball, where they form an arterial circle under the conjunctiva. Finally, they pierce the sclera immediately posterior to the cornea.

Arteria Supraorbitalis.—The supra-orbital artery accompanies the supra-orbital nerve to the forehead, where it was dissected at a previous stage (p. 47).

Arteriæ Ethmoidales.—There are two ethmoidal branches, an anterior and a posterior; they pass through the anterior and posterior ethmoidal foramina in the medial wall of the orbit. The *posterior ethmoidal artery* supplies the mucous lining of the posterior ethmoidal cells, and sends twigs to the upper part of the nose. The *anterior ethmoidal artery* is a larger branch. It runs in company with the anterior ethmoidal nerve, and gives off minute twigs at each stage of its course. Thus, in the anterior ethmoidal foramen, it gives branches to the mucous lining of the anterior ethmoidal cells and the frontal sinus; during its short sojourn in the cranial cavity it gives off a small *anterior meningeal artery*; in the nasal cavity, it gives twigs to the mucous membrane. Its terminal branch appears on the face and supplies the side of the nose.

Arteria Dorsalis Nasi.—The dorsal artery of the nose is distributed at the root of the nose, and anastomoses with the angular branch of the external maxillary artery.

Arteria Frontalis.—The frontal artery accompanies the supra-trochlear nerve to the forehead, where it has been dissected already (p. 47).

Venæ Ophthalmicæ.—As a general rule there are two ophthalmic veins, superior and inferior. The *superior ophthalmic vein* is the larger of the two and it accompanies the artery. It takes origin at the root of the nose, where it communicates with the angular vein. The *inferior ophthalmic vein* lies below the level of the optic nerve, and it is brought into communication with the pterygoid venous plexus by an offset which passes through the inferior orbital fissure. The two ophthalmic veins receive numerous tributaries during their course through the orbit; finally they pass between the two heads of the lateral rectus muscle, and through the superior orbital fissure, to open into the cavernous sinus, either separately or by a common trunk.

Musculi Recti et Obliqui Oculi.—Associated with the origins of the recti muscles of the eyeball are two tendinous

arches, a superior and an inferior. Both are attached laterally to a projection on the great wing of the sphenoid bone at the lateral margin of the superior orbital fissure. The two bands diverge from one another as they pass medially across the superior orbital fissure, the upper band extending to the superior margin, and the lower to the inferior margin of the optic foramen. The superior rectus, which is the thinnest of the four recti, springs from the medial part of the upper band; the inferior rectus, which is thicker but smaller than the superior, springs from the middle part of the lower band. The lateral and longest rectus, which is thicker than either the superior or inferior, arises by two heads, one from the lateral part of the upper band, and one from the lateral part of the lower band. The interval between the two heads is traversed by the two divisions of the oculo-motor nerve, the naso-ciliary nerve, the abducens nerve, and the ophthalmic veins. The medial rectus, which is the shortest and thickest of all the recti, springs from the medial part of the lower band. The superior oblique springs from the body of the sphenoid, between the superior and medial recti. The origin of the inferior oblique lies near the anterior margin of the orbital cavity, entirely away from the other muscles which move the eyeball. It arises from the orbital plate of the maxilla close to the lower and medial angle of the orbital cavity.

Dissection.—To display the attachments of the ocular muscles which arise at the apex of the orbital cavity divide the optic nerve close to the optic foramen, and turn the eyeball forwards. Then define the origin of each muscle, but take care not to injure the structures which pass between the upper and lower heads of the lateral rectus. Next, replace the eyeball in position and display the inferior oblique which lies in the anterior part of the orbital cavity and is best dissected from the front. Evert the lower eyelid and make an incision through the conjunctiva, along the level of its reflection from the eyelid to the eyeball. A little dissection in the floor of the anterior part of the orbit and the removal of some fat will expose the inferior oblique muscle, as it passes laterally and backwards to gain the lateral surface of the sclera.

After the origins of the muscles have been satisfactorily displayed study first the arrangement of the nerves which pass through the superior orbital fissure, next the insertions of the muscles which move the eyeball, and finally the remaining structures which lie in the orbital cavity.

Arrangement of the Nerves in the Superior Orbital Fissure.—The various nerves met with in the dissection of

the cavernous sinus can now be traced into the orbital cavity, and the dissector will note that the arrangement of the nerves in the superior orbital fissure is somewhat different from that in the sinus.

The lacrimal, frontal, and trochlear nerves enter the orbit above the upper head of the lateral rectus muscle, on very much the same plane (Fig. 96). The other nerves enter between the heads of the lateral rectus—the superior division of the oculo-motor nerve occupying the highest place; next comes the naso-ciliary nerve; then the inferior division of the oculo-motor nerve; and the abducent nerve is the lowest.

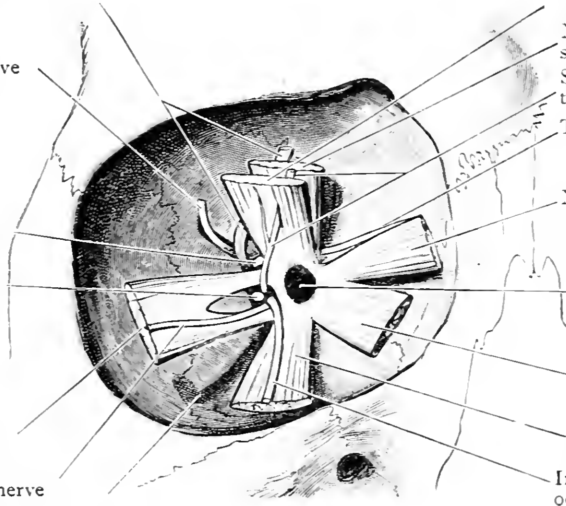

FIG. 96.—Diagram of the Orbital Cavity, and of the origin of the ocular muscles in relation to the optic foramen and the superior orbital fissure, and the nerves that traverse the fissure.

Insertions of the Muscles which move the Eyeball.—The recti are inserted into the sclera, 6 to 8 mm. (about quarter of an inch) behind the cornea. The medial rectus has the most anterior insertion, and both the medial and lateral recti are attached a little further forwards than the superior and inferior recti. The insertions of the superior and inferior oblique muscles are both much further back than the insertions of the recti, behind the transverse vertical plane which divides the eyeball into equal anterior and posterior parts, and mainly lateral to an antero-posterior vertical plane which divides the eyeball into equal lateral and medial halves.

Nervus Oculomotorius.—The two divisions of the oculomotor nerve enter the orbit through the superior orbital fissure, between the two heads of the lateral rectus. The *superior division* has been traced to the rectus superior and the levator palpebræ superioris. The *inferior division* is larger. It almost immediately divides into three branches,

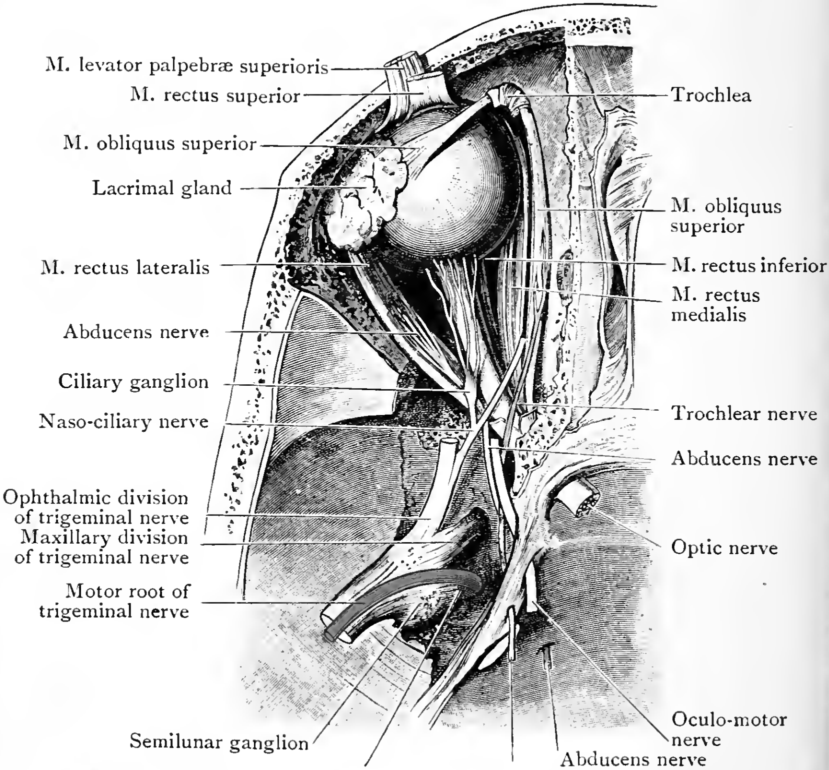

FIG. 97.—Dissection of the Orbit and the Middle Cranial Fossa. Both roots of the fifth nerve, with the semilunar ganglion, are turned laterally.

for the supply of the rectus medialis, the rectus inferior, and the obliquus inferior. The nerves to the two recti enter the ocular surfaces of the muscles; the nerve to the inferior oblique is prolonged forwards, in the interval between the rectus inferior and rectus lateralis, and enters the posterior border of the inferior oblique muscle. Soon after its origin this branch gives the *short motor root* to the ciliary ganglion.

Nervus Abducens.—The abducens nerve will be found closely applied to the ocular surface of the lateral rectus. It

enters the orbit through the interval between the heads of lateral rectus muscle, and it supplies the lateral rectus only.

Musculus Obliquus Inferior.—The inferior oblique muscle arises from a small depression on the orbital surface of the maxilla, immediately lateral to the opening of the naso-lacrimal duct. It passes laterally, below the inferior rectus muscle, and, inclining slightly backwards, ends in a thin membranous tendon, which gains insertion into the lateral aspect of the sclera of the eyeball under cover of the rectus lateralis. The insertion is not far from that of the superior oblique. The inferior oblique is supplied by the *inferior division* of the *oculo-motor nerve*. It turns the eyeball so that the centre of the cornea is directed upwards and laterally.

Fascia Bulbi (O.T. **Capsule of Tenon**).—The connections of the fibrous sheath of the eyeball are somewhat complicated, and they cannot be satisfactorily displayed, in every detail, in an ordinary dissection. The fascia may be studied from a threefold point of view—(1) in its connection with the eyeball; (2) in its connections with the muscles inserted into the globe of the eye; and (3) in its connections with the walls of the orbit.

The relation which the fascia bulbi bears to the eyeball is very simple. The membrane is spread over the posterior five-sixths of the globe—the cornea alone being free from it. *Anteriorly*, it lies in relation with the ocular conjunctiva, with which it is intimately connected, and it ends by blending with the conjunctiva close to the margin of the cornea. *Posteriorly*, it fuses with the sheath of the optic nerve where the nerve pierces the sclera. The internal surface of the membrane (*i.e.* the surface towards the globe of the eye) is smooth, and is connected to the eyeball by some soft, yielding, and humid areolar tissue, the interval between them constituting, in fact, an extensive lymph space. Its external surface is in contact posteriorly with the orbital fat, to which it is loosely adherent; and it is firmly attached to the ocular conjunctiva more anteriorly. It obviously, therefore, forms a membranous socket in which the eyeball can rotate with the greatest freedom.

The tendons of the various ocular muscles are inserted into the eyeball within the fascia bulbi, and they gain its interior by piercing the fascia opposite the equator of the globe (Fig. 98). The lips of the openings through which

the four recti muscles pass are prolonged backwards upon the muscles, in the form of sheaths, much in the same manner that the internal spermatic fascia is prolonged upon the spermatic cord from the abdominal inguinal ring. The sheaths gradually become more and more attenuated, until at last they blend with the perimysium of the muscular bellies. In the case of the superior oblique muscle the corresponding prolongation is related only to the reflected portion of the tendon; and it ends by becoming attached to the fibrous pulley through which the tendon passes. The sheath of the inferior oblique may be traced upon the muscle as far as the floor of the orbit. The ocular edge of each of the four apertures through which the recti muscles pass is strengthened by a slip of fibrous tissue (Lockwood), and as the fascia bulbi is firmly bound to the bony wall of the orbit at various points these slips act as pulleys, and protect the globe of the eye from pressure during contraction of the muscles. The aperture for the superior oblique is not furnished with such a slip, and it is doubtful if the opening for the inferior oblique muscle possesses one.

Dissection.—An admirable view of the relations which the fascia bulbi presents to the eyeball and the tendons of the ocular muscles can be obtained by the following dissection:—Divide the lateral commissure of the eyelid up to the margin of the orbital opening. Pull the eyelids widely apart, so as to expose as much as possible of the anterior face of the eyeball. Next, divide the conjunctiva, by a circular incision, just beyond the cornea. Along that line the fascia bulbi is so intimately connected with the conjunctiva that it is divided at the same time. Now raise carefully both conjunctiva and fascia bulbi from the surface of the eyeball, and spread them out round the orbital opening, as is depicted in Fig. 98. The openings in the fascia bulbi for the tendons of the ocular muscles and the thickened margins of the apertures are well seen. Note also the sheaths which are given to the muscles.

Check and Suspensory Ligaments.—The connections of the fascia bulbi to the walls of the orbital cavity are somewhat complicated. The *suspensory ligament* (Lockwood) plays an important part in supporting the eyeball. It stretches across the anterior part of the orbit, after the fashion of a hammock; its two extremities are narrow, and are attached respectively to the zygomatic and lacrimal bones. Below the eyeball it widens out and blends with the fascia bulbi. The *lateral* and *medial check ligaments*

also constitute bonds of union between the fascia bulbi and the orbital wall. They are strong bands which pass from the sheaths around the lateral and medial recti muscles to obtain attachment to the zygomatic and lacrimal bones respectively, where they are brought into association with the extremities of the suspensory ligament. The function of the check ligaments is to limit the contraction of the medial and lateral recti muscles, and thus prevent excessive rotation of the eyeball in a lateral or medial direction. There is a similar but less direct provision by means of which the actions of the superior and inferior recti muscles are limited.

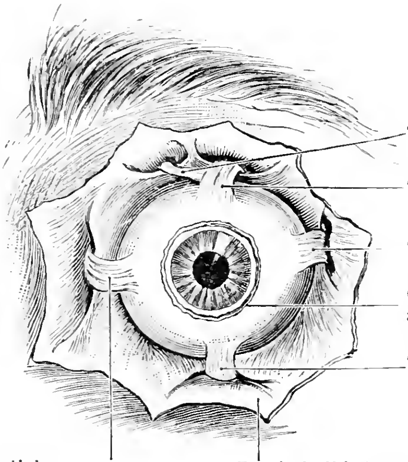

FIG. 98.—Dissection of the Fascia Bulbi from the front.

The action of the superior rectus is checked through an intimate connection with the levator palpebræ superioris in the anterior part of the orbit; the action of the inferior rectus is checked through a connection with the suspensory ligament.

Dissection.—In order that the zygomatic branch of the maxillary division of the trigeminal nerve may be displayed in its course through the orbit, the orbital contents must be removed. The nerve will then be found in the midst of a little soft fat in the angle between the floor and lateral wall of the orbit.

Nervus Zygomaticus (O.T. **Temporo-Malar**).—The zygomatic nerve is small. It arises, in the infra-temporal fossa, from the maxillary division of the trigeminal nerve. It enters the orbit through the inferior orbital fissure, and almost

immediately divides into two terminal branches — the zygomatico-temporal and the zygomatico-facial.

Ramus Zygomaticotemporalis. — The zygomatico-temporal branch runs forwards and upwards upon the lateral wall of the orbit, under cover of the periosteum, and, after receiving a communicating twig from the lacrimal nerve, it enters the zygomatico-orbital canal of the zygomatic bone. That canal conducts it to the anterior part of the temporal region, where it has been examined already (pp. 19 and 170).

Ramus Zygomaticofacialis.—The zygomatico-facial branch also enters a zygomatico-orbital canal, and is finally conducted to the face by the zygomatico-facial canal which traverses the zygomatic bone (p. 19).

PREVERTEBRAL REGION.

The following are the structures to be displayed in the prevertebral area :—

Prevertebral muscles.
Intertransverse muscles.
Cervical nerves.
Vertebral artery.
Vertebral vein.
Vertebral and cranio-vertebral articulations.

Dissection.—To separate the anterior part of the head, with the pharynx, from the posterior part and the vertebral column a somewhat complicated dissection is necessary. Place the head upside down, so that the cut margin of the skull rests upon the table; divide the common carotid artery, the internal jugular vein, the vagus nerve, and the sympathetic trunk, on each side, at the level of the neck of the first rib; pull the trachea and œsophagus, together with the great blood-vessels and nerves, away from the anterior surface of the vertebral column. The separation must be effected right up to the base of the skull. At that point great caution must be observed; otherwise, the pharyngeal wall or the insertions of the prevertebral muscles will be damaged. The base of the skull having been reached, the point of the knife should be carried across the basilar portion of the occipital bone, between the pharynx and the prevertebral muscles, to divide the thick investing periosteum.

The basilar portion of the occipital bone must now be divided by means of a chisel. Still retaining the part upside down, place the skull so that its floor rests upon the end of a wooden block. Then apply the edge of the chisel to the under surface of the basilar portion of the occipital bone, adjust it accurately in the interval between the pharyngeal wall and the prevertebral muscles, and with a wooden mallet drive it through the base of the skull, inclining it, at the same time, slightly backwards.

The next step in the dissection consists in making two saw-cuts through the cranial wall. The head having been placed upon its side, the saw must be applied to the lateral aspect of the skull, half an inch posterior to the mastoid process, and be carried obliquely forwards and medially to reach a point immediately posterior to the jugular foramen. A similar saw-cut must be made upon the opposite side of the head.

To complete the dissection the dissector must again use the chisel. Placing the preparation so that the floor of the cranial cavity looks upwards, divide the base of the skull, on each side, in the interval between the petrous portion of the temporal bone and the basilar portion of the occipital bone. Anteriorly, this cut should reach the lateral extremity of the incision already made through the basilar portion; whilst posteriorly, it should be carried to the medial side of the jugular foramen to reach the medial end of the corresponding saw-cut. When that has been done upon both sides of the basilar portion, the anterior part of the skull, carrying the pharynx and the great blood-vessels and nerves, can be separated from the posterior part of the skull and cervical portion of the vertebral column. The only large nerve which will be divided is the hypoglossal, but, as it is cut close to the basis cranii, and above its connection with the ganglion nodosum of the vagus, it retains its position.

The pharynx and anterior portion of the skull should now be covered with a piece of cloth soaked in preservative solution, and the whole enveloped in an oil-cloth wrapper. It can then be laid aside until the dissection of the prevertebral region and the ligaments of the cervical vertebræ and the occiput has been completed.

Returning to the posterior part of the skull and the cervical portion of the vertebral column, the dissector should proceed to define the attachments of the muscles which lie anterior to the transverse processes and the bodies of the vertebræ. They are three in number on each side, viz. :—

1. The longus colli.
2. The longus capitis (O.T. rectus capitis anticus major).
3. The rectus capitis anterior (O.T. anticus minor).

Musculus Longus Colli.—The longus colli is the most powerful of the prevertebral muscles of the neck, and it lies nearest to the median plane. Its connections are somewhat intricate, but when it has been thoroughly cleaned it will be seen to consist of three portions—viz., upper and lower oblique parts, and a middle vertical part.

The *lower oblique* division arises from the lateral aspect of the bodies of the upper two or three thoracic vertebræ. It extends upwards, and slightly laterally, and ends in two tendinous slips which are inserted into the anterior tubercles of the transverse processes of the fifth and sixth cervical vertebræ. In the interval between that portion of the longus colli and the scalenus anterior, the vertebral artery will be

seen. The *upper oblique* part arises by three tendinous slips from the anterior tubercles of the transverse processes of the third, fourth, and fifth cervical vertebræ; it tapers somewhat as it proceeds upwards and medially to obtain a pointed and tendinous insertion into the anterior tubercle of

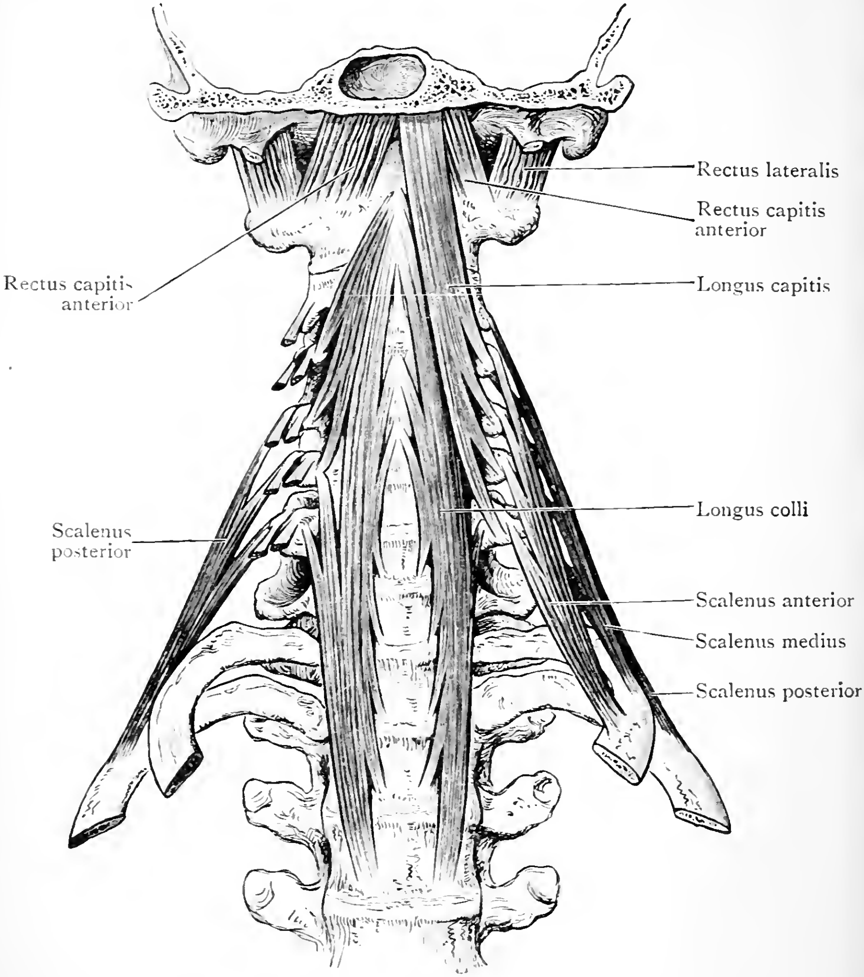

FIG. 99.—Prevertebral Muscles of the Neck. On the right side the longus capitis has been removed. (Paterson.)

the atlas. The *vertical part* of the muscle is much the largest of the three divisions. It lies along the medial side of the oblique portions, and is intimately connected with both of them. It arises, in common with the inferior oblique part, by two or three slips from the sides of the bodies of the

upper two or three thoracic vertebræ; and it derives additional slips of origin from the bodies of the lower two cervical vertebræ; lastly, its lateral border is reinforced by slips from the transverse processes of the lower three or four cervical vertebræ. It passes vertically upwards, and is inserted upon the medial side of the upper oblique part of the muscle by three tendinous processes, which obtain attachment to the bodies of the second, third, and fourth cervical vertebræ. It is supplied by the anterior rami of the cervical nerves. It bends the neck forwards.

Longus Capitis (O.T. **Rectus Capitis Anticus Major**).—The longus capitis is an elongated muscle which arises by four tendinous slips from the anterior tubercles of the transverse processes of the third, fourth, fifth, and sixth cervical vertebræ. It is inserted, anterior to the foramen magnum, upon the under aspect of the basilar portion of the occipital bone. To reach its insertion the muscle inclines slightly medially as it ascends upon the anterior aspect of the vertebral column (Fig. 99). It is supplied by twigs from the *first loop* of the *cervical plexus.* It bends the head forwards.

Rectus Capitis Anterior (O.T. **Anticus Minor**).—The rectus capitis anterior is a small muscle. It is partly concealed by the upper portion of the longus capitis, which should be detached from its insertion, and turned downwards so as to bring the capitis anterior fully into view. It arises from the anterior aspect of the lateral mass of the atlas and, proceeding upwards and medially, is inserted into the under surface of the basilar portion of the occipital bone, posterolateral to the longus capitis (Fig. 99). It is supplied by a filament from the *first loop* of the *cervical plexus.* It bends the head forwards.

Before proceeding farther, the dissector should again examine the attachments of the scalene muscles (*v.* p. 233).

Musculi Intertransversarii.—To obtain a proper display of the intertransverse muscles the prevertebral and scalene muscles must be removed. The intertransverse muscles, on each side, consist of seven pairs of small fleshy slips which connect the bifid extremities of the cervical transverse processes; they are the anterior and posterior intertransverse muscles. Each anterior muscle is attached to the anterior tubercles of two adjacent transverse processes; whilst the posterior extends between the posterior tubercles. The

highest pair of muscular slips lies between the atlas and the epistropheus ; the lowest pair connects the transverse process of the seventh cervical vertebra with the transverse process of the first thoracic vertebra.

Nervi Cervicales.—The cervical spinal nerves have a very definite relation to the intertransverse muscles. The anterior rami of the lower seven nerves make their appearance, by passing laterally, *between* the two corresponding muscles. The posterior divisions of the same nerves turn backwards, medial to the posterior muscles.

The upper two cervical nerves emerge from the vertebral canal differently from the others. They pass laterally over the posterior arch of the atlas and the vertebral arch of the epistropheus, respectively, behind the articular processes, whilst the lower nerves are situated in front of the articular processes.

The anterior ramus of the first cervical nerve passes forwards medial to the rectus capitis lateralis, and then turns downwards to join the anterior ramus of the second cervical nerve, with which it forms the first loop of the cervical plexus. The posterior ramus passes backwards into the sub-occipital triangle. The anterior ramus of the second cervical nerve passes laterally between the first pair of intertransverse muscles, and the posterior ramus runs backwards medial to the first posterior intertransverse muscle.

Dissection.—The vertebral artery as it traverses the succession of foramina in the transverse processes of the cervical vertebræ should now be exposed. Remove the intertransverse muscles as well as the muscles still attached to the transverse process of the atlas—viz., the rectus lateralis, the inferior oblique, and the superior oblique. The anterior tubercles and the costal portions of the transverse processes of the third, fourth, fifth, and sixth cervical vertebræ should then be snipped off with the bone forceps.

Arteria Vertebralis.—The vertebral artery is a vessel of great importance, for, together with its fellow of the opposite side and the basilar artery, which is formed by their union, it supplies the hind-brain, the mid-brain, and the posterior parts of the cerebral hemispheres, and it helps to supply the spinal medulla. It commences at the root of the neck, as a branch of the first part of the subclavian artery, and it runs upwards, through the transverse processes of the upper six cervical vertebræ, to the base of the skull. It enters the skull through the foramen magnum and unites, in the posterior fossa of the

cranium, at the lower border of the pons, with its fellow of the opposite side to form the basilar artery. On account of its varying relations it is divided into four parts. The *first part*, which extends from the subclavian artery to the transverse process of the sixth cervical vertebra, has been seen already (p. 154). It lies between the longus colli medially, the scalenus anterior laterally, the transverse process of the seventh cervical vertebra and the inferior cervical ganglion of

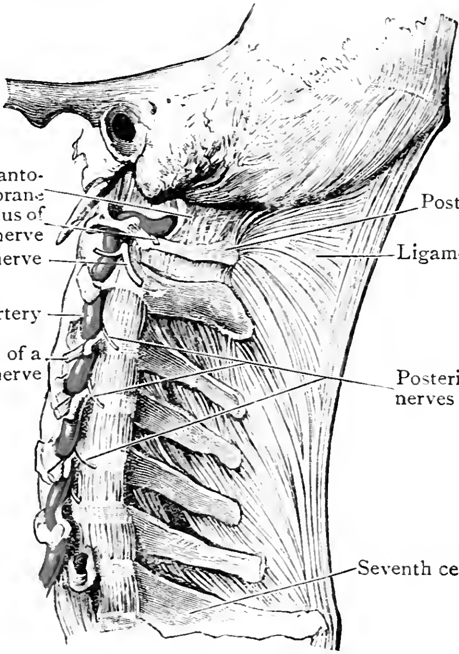

FIG. 100.—Dissection of the Ligamentum Nuchæ and of the Vertebral Artery in the Neck.

the sympathetic posteriorly, and the vertebral vein and the common carotid artery anteriorly (Figs. 53, 54).

The *second part*, now exposed, commences where the artery enters the transverse process of the sixth cervical vertebra. It passes vertically upwards, through the series of foramina transversaria, till it reaches the foramen in the transverse process of the epistropheus. In that it runs laterally, as well as upwards, to gain the foramen in the more laterally placed transverse process of the atlas; and, as it emerges upon the upper aspect of the atlas (Figs. 56, 100), the *third part* commences and curves round the lateral and

posterior aspects of the corresponding upper articular process of the atlas, in a groove upon the upper surface of its posterior arch (Figs. 20, 38). As soon as it has passed under cover of the lateral margin of the posterior atlanto-occipital membrane it becomes the *fourth part.* The fourth part turns upwards, pierces the dura mater, and passes into the skull through the foramen magnum, anterior to the uppermost digitation of the ligamentum denticulatum; then, turning antero-medially, between the hypoglossal nerve above and the first cervical nerve below, it passes to the anterior surface of the medulla oblongata, and, as already stated, joins its fellow of the opposite side at the lower border of the pons (Figs. 37, 144).

Relations.—The relations of the first part have already been sufficiently considered. The second part lies in and between the transverse processes of the cervical vertebræ, medial to the intertransverse muscles, lateral to the bodies of the vertebræ, and anterior to the anterior rami of the cervical nerves as they pass laterally. It is surrounded not only by the sympathetic nerve plexus derived from the inferior cervical ganglion, which accompanies all parts of the artery, but also by a venous plexus which terminates, below, as the vertebral vein or veins. The third part of the artery lies on the posterior arch of the atlas in the anterior boundary of the sub-occipital triangle. As it turns backwards, from the foramen in the transverse process of the atlas, the anterior ramus of the first cervical nerve lies to its medial side, between it and the lateral mass of the atlas; and, as it turns medially, posterior to the upper articular facet of the atlas, the trunk of the first cervical nerve lies below it, on the posterior arch of the atlas, and the posterior ramus enters the triangle from beneath its lower border. For the relations of the fourth part see the preceding paragraph and pp. 117, 382.

Branches.—No branch of importance is given off from the first part. The second part gives off lateral spinal (p. 90) and muscular branches. The branches from the third part are muscular twigs, and branches to anastomose with twigs from the occipital and the deep cervical arteries. The fourth part gives off a meningeal branch before it perforates the dura mater and, afterwards, a series of branches to the central nervous system (see pp. 382, 383).

Vena Vertebralis.—Only the first part of the vertebral artery is accompanied by a definite vertebral vein. There are no accompanying veins with the fourth part of the artery, but a plexus is formed round the commencement of the third part, by the union of tributaries from the venous plexus in the vertebral canal and from the plexus of veins in the sub-occipital triangle. The plexus accompanies the second part of the artery through the transverse processes of the cervical vertebræ; it anastomoses with the venous plexuses in the vertebral canal; and it terminates, below, as one or two vertebral veins. The vertebral veins accompany the first part of the artery and end in the posterior aspect of the commencement of the innominate vein.

Dissection.—The muscles must now be completely removed, in order that the vertebral and cranio-vertebral joints, and the ligaments in connection with the cervical portion of the vertebral column, may be examined.

THE JOINTS OF THE NECK.

The epistropheus, atlas, and occipital bone present a series of articulations in which the uniting apparatus is very different from that of the vertebræ below.

Articulations of the Lower Five Cervical Vertebræ.—The lower five cervical vertebræ are united together very much upon the same plan as the vertebræ in other regions of the vertebral column. The bodies and the vertebral arches are connected by distinct articulations and special ligaments.

Three separate joints may be said to exist between the opposed surfaces of the *bodies* of two adjacent cervical vertebræ—viz., a central synchondrosis and two small collateral diarthrodial joints.

The *synchondrosis* occupies by far the greatest part of the interval between the vertebral bodies, and it presents the usual characters of such an articulation. The opposed bony surfaces are coated with a thin layer of hyaline or encrusting cartilage, and are connected together by an interposed disc of fibro-cartilage. The intervertebral fibro-cartilages are distinctly deeper anteriorly than posteriorly, and upon that circumstance the cervical curvature of the column in great measure depends.

The two *diarthrodial joints* are placed, one on each side,

where the disc of fibro-cartilage is absent. They are of small extent, and are confined entirely to the intervals between the projecting lateral lips of the upper surface of the body and the bevelled-off lateral margins of the lower surface of the vertebral body immediately above. The bony surfaces are coated with encrusting cartilage, and are separated by a synovial cavity enclosed by a feeble articular capsule.

The *ligaments* which bind the bodies of the lower five cervical vertebræ together are the direct continuation upwards of the anterior and the posterior longitudinal ligaments of the vertebræ. When the medulla spinalis was removed, the laminæ of the vertebræ, below the epistropheus, were

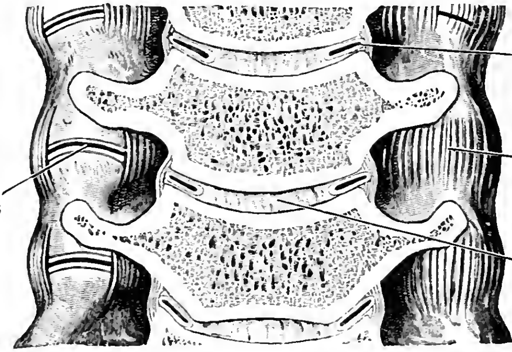

FIG. 101.—Frontal section through bodies of certain of the Cervical Vertebræ.

taken away, so that very little dissection will be required to make out the connections of both of the ligaments mentioned. The *anterior longitudinal ligament* is a strong band placed on the anterior faces of the vertebral bodies. It is more firmly fixed to the intervening intervertebral fibro-cartilages than to the bones. The *posterior longitudinal ligament*, which lies on the posterior aspects of the vertebral bodies, constitutes the anterior boundary of the vertebral canal. In the cervical region it completely covers the bodies and does not present the denticulated appearance which is so characteristic lower down. It is attached chiefly to the fibro-cartilages and the adjacent margins of the bones.

The *vertebral arches* of the lower five cervical vertebræ are bound together by (*a*) the articulations between the articular processes; (*b*) ligamenta flava; (*c*) interspinous ligaments, and (*d*) intertransverse ligaments; (*e*) ligamentum nuchæ.

The *joints* between the opposing articular processes are of the diarthrodial variety. The surfaces of bone are coated with cartilage; there is a joint cavity surrounded by a distinct articular capsule, lined with a synovial stratum. The capsule is more laxly arranged in the neck than in the lower regions of the vertebral column.

The *ligamenta flava* may be examined on the laminæ which were removed for the display of the spinal medulla, and which the dissector was directed to retain. They fill up the gaps between the laminæ of the vertebræ, and can be seen best when the anterior aspect of the specimen is viewed.

Ligamenta Flava.—The ligamenta flava are composed of

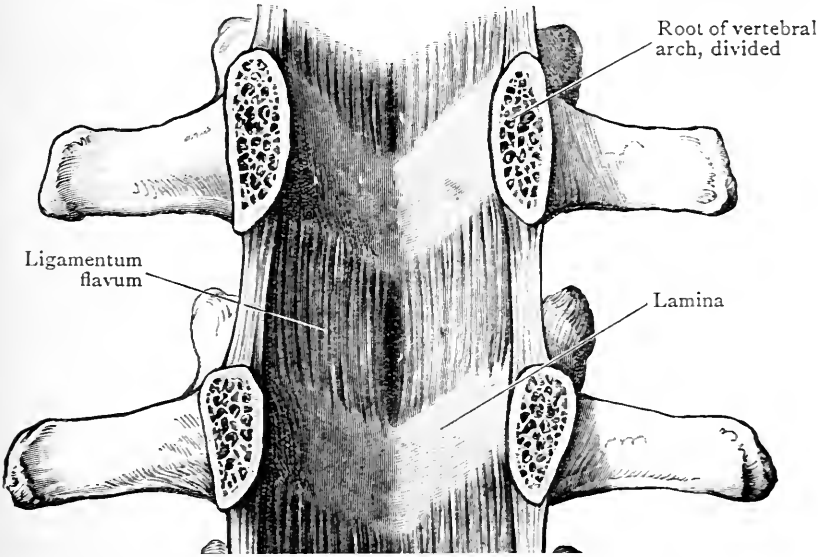

FIG. 102.—The Ligamenta Flava in the Lumbar Region.

yellow elastic tissue. Each is attached superiorly to the anterior surface and inferior margin of the lamina of the vertebra above, whilst inferiorly it is fixed to the posterior surface and superior margin of the lamina of the vertebra next below. The laminæ and the ligaments form, together, a smooth, even, posterior wall for the vertebral canal. Each ligament extends from the posterior part of the articular processes to the median plane, where its free thickened median border is in contact with its fellow of the opposite side. The median slit between them, in the space between each pair of vertebral arches, is filled with some lax connective

tissue, which allows the egress from the vertebral canal of some small veins. The width of the ligaments in the different regions of the vertebral column depends upon the size of the vertebral canal. Therefore, they are widest in the neck and in the lumbar part of the column. The ligamenta flava, by virtue of their great strength and elasticity, are powerful agents in maintaining the curvatures of the vertebral column; they also give valuable aid to the muscles in restoring the vertebral column to its original position after it has been bent in a ventral direction.

The *interspinous ligaments* are most strongly developed in the lumbar region, where they fill up the intervals between the adjacent margins of contiguous spinous processes. In the thoracic region, and more so in the neck, they are very weak.

The *supraspinous ligaments* are thickened bands which connect the summits of the spinous processes. In the neck they are replaced by the ligamentum nuchæ (p. 67).

The *intertransverse ligaments* are feebly marked in the cervical region and extend chiefly between the anterior bars of the transverse processes.

Articulations of the Epistropheus, Atlas, and Occipital Bone.—The articulations which exist between the atlas and the occipital bone and the atlas and the epistropheus all belong to the diarthrodial class. Between the atlas and epistropheus (O.T. axis) there are three such joints—viz., a pair between the opposed articular processes, and a third between the anterior face of the dens and the posterior face of the anterior arch of the atlas. Between the atlas and occipital bone there is a pair of joints—viz., between the occipital condyles and the elliptical cavities upon the upper aspects of the lateral masses of the atlas. In addition, the epistropheus is attached to the occipital bone by ligaments.

The ligaments connecting the three bones together may be divided into three main groups, as follows:—

Ligaments connecting atlas with epistropheus, . . .	Anterior longitudinal. Ligamenta flava. Capsular. Transverse portion of cruciate ligament with inferior crus. Accessory ligaments of the atlanto-epistropheal joints.

Ligaments connecting occipital bone with atlas, . .	Anterior longitudinal ligament. Anterior atlanto-occipital membrane. Posterior atlanto-occipital membrane. Transverse part of cruciate ligament with superior crus. Capsular.
Ligaments connecting occipital bone with epistropheus, ...	Membrana tectoria. Superior and inferior crus of the cruciate ligament. Alar. Apical.

Ligamentum Longitudinale Anterius (Fig. 103).—The anterior longitudinal ligament is a continuation upwards of the common anterior longitudinal ligament. Below, it is attached to the anterior aspect of the body of the epistropheus, whilst above, it is fixed to the anterior arch of the atlas. It is thick and strong in the middle, but thins off towards the sides.

Ligamenta Flava.—The yellow ligaments fill the interval between the laminæ of the epistropheus and the posterior arch of the atlas, to the contiguous margins of which they are attached. They are broader and more membranous than the ligamenta flava at lower levels.

Capsulæ Articulares.—The articular capsules are somewhat lax, and are attached to the margins of the articular processes.

Membrana Atlanto-Occipitalis Anterior (Fig. 103).—The anterior occipito-atlantal membrane extends from the upper border of the anterior arch of the atlas to the under surface of the basilar portion of the occipital bone, anterior to the foramen magnum. On each side of the median plane it is thin and membranous, and stretches laterally so as to abut against the atlanto-occipital articular capsule. In the median plane it is strengthened by the upper part of the anterior longitudinal ligament.

Membrana Atlanto-Occipitalis Posterior.—The thin and weak posterior occipito-atlantal membrane occupies the gap between the posterior arch of the atlas and the posterior border of the foramen magnum, to both of which it is attached. It is very firmly connected with the dura mater, and on each side it reaches the atlanto-occipital articular capsule. Each of its lateral borders forms an arch over the groove, posterior to the upper articular facet of the atlas, in which the vertebral artery and the first cervical nerve are lodged. It is not uncommon to find the borders ossified.

Atlanto-Occipital Articular Capsules.—The atlanto-occipital capsules connect the occipital condyles with the lateral masses of the atlas. They completely surround the joints, and are connected anteriorly with the anterior atlanto-occipital membrane, and posteriorly with the posterior atlanto-occipital membrane.

The occipital bone, therefore, around the foramen magnum is attached by special ligaments to each of the four portions

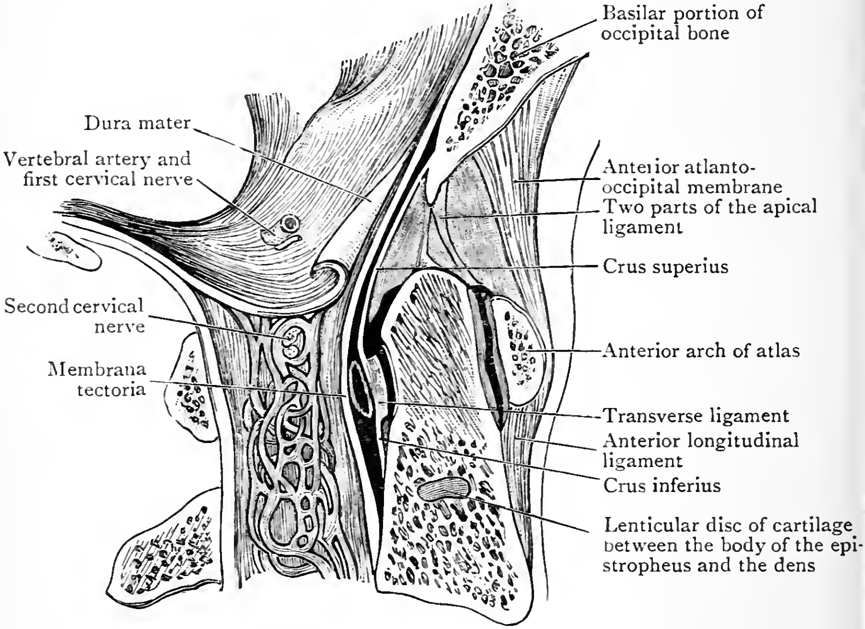

FIG. 103.—Median section through the Basilar Portion of Occipital Bone, the Atlas and the Epistropheus. (From Luschka, slightly modified.)

Between the membrana tectoria and the transverse ligament a small synovial bursa may be seen.

of the atlas—viz., to the anterior arch, to the two lateral masses, and to the posterior arch.

> ***Dissection.***—The remaining ligaments are placed within the vertebral canal, in connection with its anterior wall. For their proper display it is necessary therefore to remove, with the bone forceps, the laminæ of the epistropheus and the posterior arch of the atlas. The squamous part of the occipital bone also must be taken away, by sawing it through, on each side, immediately posterior to the jugular process and the condyle, carrying the saw cut into the foramen magnum. The upper part of the tube of dura mater, which still remains in the vertebral canal, must next be carefully detached. When that has been done,

a broad membranous band stretching upwards over the posterior aspect of the body and dens of the epistropheus is displayed. This is the membrana tectoria.

The Membrana Tectoria (O.T. **Posterior Occipito-axial Ligament**).—The tectorial membrane is a broad ligamentous sheet which is attached, below, to the posterior aspect of the body of the epistropheus, where it is continuous with the posterior longitudinal ligament of the vertebræ. It extends upwards, covering the dens and the anterior margin of the foramen magnum, and is attached, above, to the superior grooved surface of the basilar portion of the occipital bone.

Dissection.—Detach the tectorial membrane from the epistropheus and throw it upwards upon the basilar portion of the occipital bone. By that proceeding the accessory ligaments of the atlanto-epistropheal joints and the cruciate ligament will be brought into view, and very little further dissection is required to define them.

Accessory Atlanto-epistropheal Ligaments (Fig. 104).—The accessory atlanto-epistropheal ligaments are two strong bands which take origin from the posterior aspect of the body of the epistropheus, close to the base of the dens. Each band passes upwards and laterally, and is attached to the medial and posterior part of the corresponding lateral mass of the atlas. To a certain extent they assist the alar ligaments in limiting the rotary movements of the atlas upon the epistropheus.

Ligamentum Cruciatum (Fig. 104).—The cruciate ligament is composed of a transverse and a vertical part. The transverse part is by far the most important constituent. It is a strong band which stretches from the tubercle on the medial aspect of the lateral mass of the atlas on one side to the corresponding tubercle on the opposite side. With the anterior arch of the atlas, it forms a ring which encloses the dens—the pivot around which the atlas, bearing the head, turns. It is separated from the posterior aspect of the dens by a loose synovial membrane which extends forwards, on each side, until it almost reaches the synovial membrane in connection with the median joint between the dens and the anterior arch of the atlas. Indeed, in some cases a communication exists between the two synovial cavities.

The *vertical part* of the cruciate ligament consists of an upper and a lower limb, which are termed the crura. Both

are attached to the dorsal surface of the transverse ligament. The *crus superius* is the longer and flatter of the two, and extends upwards on the posterior aspect of the dens to be attached to the upper aspect of the basilar part of the occipital bone, immediately beyond the anterior margin of the foramen magnum. The *crus inferius*, much shorter, extends downwards, and is fixed to the posterior aspect of the body of the epistropheus.

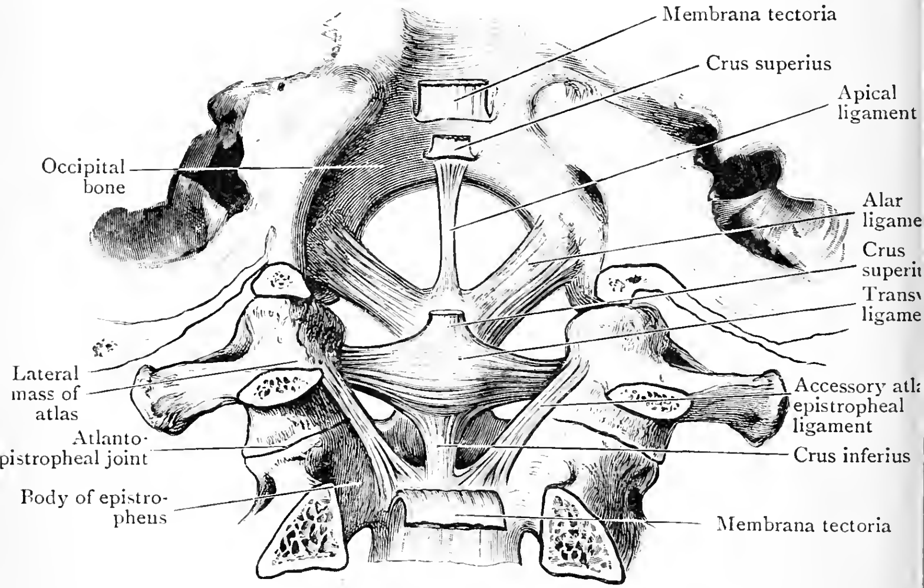

FIG. 104.—Dissection showing the posterior aspects of the Ligaments connecting the Occipital Bone, the Atlas and the Epistropheus with each other.

Dissection.—Detach the superior crus from the occipital bone, and throw it downwards. The apical ligament is thus displayed, and a better view of the alar ligaments is obtained.

Ligamentum Apicis Dentis.—The apical ligament of the dens consists of two parts—an anterior and a posterior. The *posterior part* is a rounded cord-like ligament which is attached, below, to the summit of the dens, and, above, to the anterior margin of the foramen magnum. Inasmuch as it is developed around the continuation of the notochord, from the dens to the basis cranii, it is a structure of considerable morphological interest. The *anterior part* of the apical ligament is a flat and weak band which is attached, above, to the anterior

margin of the foramen magnum at the same point as the posterior portion. Below, the two portions are separated by an interval filled with areolar tissue, and the anterior part is attached to the dens immediately above its articular facet for the anterior arch of the atlas.

Ligamenta Alaria (Fig. 104).—The alar ligaments are very powerful bands which spring, one from each side of the summit of the dens. Each passes laterally and slightly upwards to be attached to the medial aspect of the corresponding condyloid eminence of the occipital bone. The alar ligaments limit rotation of the head, and in this they are aided by the accessory atlanto-epistropheal ligaments.

Movements.—Nodding movements of the head are permitted at the atlanto-occipital articulations. Rotatory movements of the head and atlas around the dens, which acts as a pivot, take place at the atlanto-epistropheal joints. Excessive rotation is checked by the alar ligaments.

MOUTH AND PHARYNX.

The dissectors must now return to the anterior part of the skull, which had been laid aside while the dissection of the prevertebral region was being carried on. The mouth and pharynx should engage their attention in the first instance.

Mouth.—The mouth is the expanded upper part of the alimentary canal which is placed in the lower part of the face, below the nasal cavities. Its cavity is controlled by muscles which are under the influence of the will, and it is separable into two parts: a smaller external part, termed *the vestibule*, which is bounded externally by the lips and cheeks, and internally by the teeth and gums; and a large part, the *mouth proper*, which is placed within the teeth.

The mucous lining of the mouth should be thoroughly cleansed, and the two subdivisions of the cavity examined through the *oral fissure*.

Vestibulum Oris.—The *vestibule* of the mouth, which lies outside the teeth and gums, is a mere fissure-like space, except when the cheeks are inflated with air. It is into the vestibule of the mouth that the parotid ducts open (p. 164). *Above* and *below*, it is bounded by the reflection of the mucous membrane from the lips and cheeks on to the alveolar margins of the maxillæ and mandible. *Anteriorly*, it opens upon the face by means of the oral fissure; whilst

posteriorly, it communicates, on each side, with the cavity of the mouth proper through the interval between the last molar tooth and the anterior border of the ramus of the mandible. The existence of that communicating aperture is of importance in cases of spasmodic closure of the jaws, when all the teeth are in place, because through it fluids may be introduced into the posterior part of the mouth proper.

In paralysis of the facial muscles the lips and cheeks fall away from the dental arches and food is apt to lodge in the vestibule.

Cavum Oris Proprium.—The *mouth proper* is bounded, anteriorly and laterally, by the gums and teeth, whilst, posteriorly, it communicates, by means of the *isthmus of the fauces*, with the pharynx. The *floor* is formed by the tongue and the mucous membrane which connects it with the inner aspect of the mandible; the *roof* is vaulted, and is formed by the hard and the soft palates. It is into the mouth proper that the ducts of the submaxillary glands and the ducts of the sublingual glands open (p. 194). When the mouth is closed the dorsum of the tongue is usually applied more or less closely to the palate and the cavity is almost completely obliterated.

The various parts which bound the oral cavity may now be examined in turn.

Labia Oris.—The structure of the lips has, in a great measure, been examined already in the dissection of the face (p. 10). Each lip is composed of four layers: (1) Cutaneous; (2) muscular; (3) glandular; and (4) mucous. The *skin* and *mucous membrane* become continuous with each other at the free margin of the lip. The mucous membrane is reflected from the inner aspect of the upper lip to the alveolar margin of the maxillæ, and from the inner aspect of the lower lip to the mandible. In each case it is raised in the median plane in the form of a free fold termed the *frenulum.* The *muscular layer* constitutes the chief bulk of the lips. It is formed by the orbicularis oris and the various muscles which converge upon the oral fissure. Numerous *labial glands* lie in the submucous tissue which intervenes between the mucous membrane and the muscular fibres. The ducts of those glands pierce the mucous membrane and open into the vestibule. In each lip there is an arterial arch formed by the corresponding labial arteries (p. 16).

The lymph vessels of both lips join the submaxillary lymph glands, but some of the lymph vessels of the upper lip pass to the superficial parotid glands.

Buccæ.—Six layers can be distinguished in the cheeks, four of which were examined in the dissection of the face. They are—(1) Skin; (2) a fatty layer, traversed by some of the facial muscles and by the external maxillary artery; (3) the bucco-pharyngeal fascia; (4) the buccinator muscle; (5) the submucous tissue, in which lie numerous *buccal glands* similar in character to the labial glands; (6) the mucous membrane. Four or five mucous glands of larger size, termed the *molar glands*, occupy a more superficial position. They lie either external or internal to the bucco-pharyngeal fascia, close to the point where it is pierced by the parotid duct, and their ducts open into the vestibule of the mouth. The *bucco-pharyngeal fascia* is a dense membrane which covers the buccinator muscle. Above and below, it is attached to the alveolar portions of the maxilla and mandible respectively, whilst posteriorly it is continued over the pharynx. The muscles which traverse the *fatty layer* are chiefly the zygomaticus, the risorius, and the posterior fibres of the platysma. The parotid duct pierces the inner four layers of the cheek, and opens into the vestibule of the mouth, opposite the second molar tooth of the maxilla.

Gingivæ et Dentes.—The gums are covered with a smooth and vascular mucous membrane, which is firmly bound down to the subjacent periosteum of the alveolar portions of the jaws by a stratum of dense connective tissue. It is continuous, on the one hand, with the mucous membrane of the lips and cheeks, and, on the other, with the mucous membrane of the mouth proper. The gums closely embrace the necks of the teeth.

In the adult, the teeth in each jaw number sixteen. From the median line backwards, on each side, they are the two incisors, the canine, the two præmolars, the three molars.

Floor of the Mouth.—The mucous membrane is reflected from the inner aspect of the mandible to the side of the tongue; but in the anterior part of the mouth the tongue lies more or less free in the oral cavity, and there the mucous membrane stretches across the floor from one half of the mandible to the other. On each side, in the anterior region, the projection formed by the sublingual gland, *the plica sub-*

lingualis, can be distinguished. Further, if the tongue is pulled upwards, a median fold of mucous membrane will be seen to connect its under surface to the floor. It is the *frenulum linguæ*. At the sides of the frenulum the dissector must look for the openings of the submaxillary ducts. Each terminates on a papilla placed close to the side of the frenulum. More posteriorly, between the side of the tongue and the mandible and on the summit of the plica sublingualis, are the openings of the sublingual ducts.

Roof of the Mouth.—The hard and the soft palates form

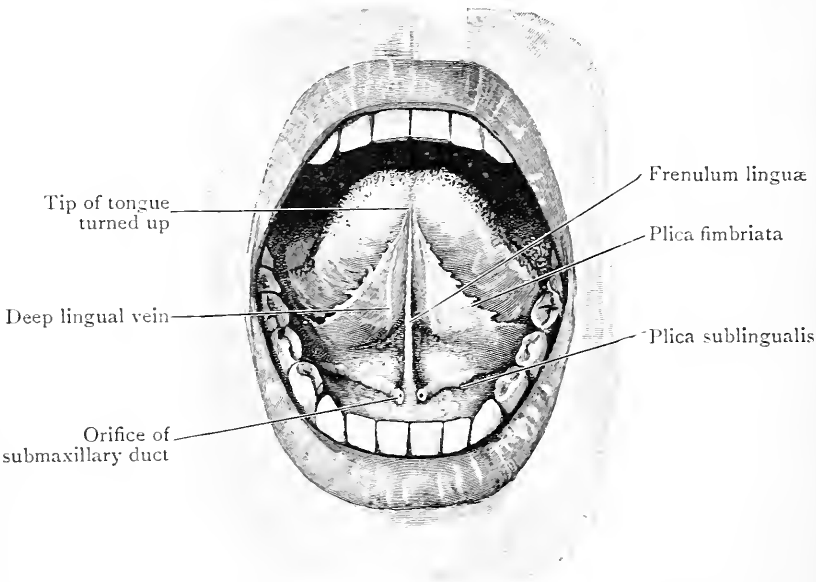

FIG. 105.—The Sublingual Region in the Interior of the Mouth.

the continuous concave and vaulted roof of the mouth (Fig. 106). Projecting from the middle of the posterior free margin of the soft palate, and resting upon the dorsum of the tongue, the *uvula* will be seen (Fig. 106). Running along the median line of both the hard and the soft palates is a raphe which terminates anteriorly, opposite the incisive foramen of the hard palate, in a slight elevation or papilla termed the *incisive papilla*. In the anterior part of the hard palate the mucous membrane, on each side of the raphe, is thrown into three or four transverse hard corrugations or ridges; more posteriorly it is comparatively smooth. By carefully palpating the postero-lateral angles of the palate the dissector

will be able to feel the hamuli of the medial pterygoid laminæ.

Isthmus Faucium.—*The isthmus of the fauces* is the name given to the communication between the mouth proper and the pharynx (Fig. 106). To obtain a good view of it the mouth must be well opened and the tongue depressed. The isthmus faucium and the parts which bound it can be examined best in the living subject, and the dissector should study his own isthmus faucium with the aid of a looking-glass

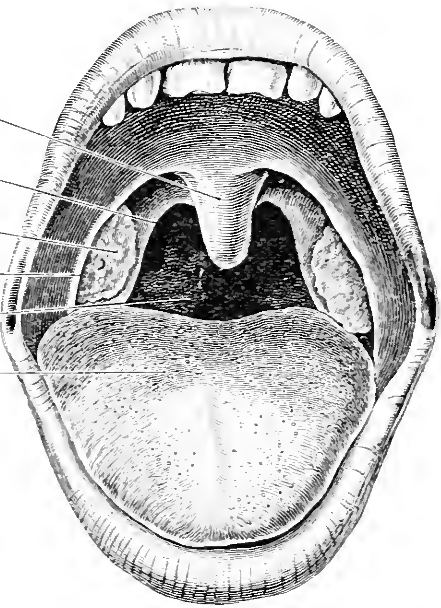

FIG. 106.—Isthmus of the Fauces as seen through the widely opened Mouth. The palatine tonsils, in the subject from which this drawing was made, were somewhat enlarged.

(Fig. 106). It is bounded above by the soft palate, below by the dorsum of the tongue, and on each side by a curved fold of mucous membrane, termed the arcus glossopalatinus (O.T. anterior pillar of the fauces).

Each *glosso-palatine arch* descends from the posterior part of the inferior surface of the soft palate and, inclining forwards as it descends, it ends upon the side of the posterior part of the tongue. It encloses the glosso-palatinus muscle.

The *pharyngo-palatine arches* which are also described as boundaries of the isthmus of the fauces lie, in reality, on the side wall of the oral part of the pharynx. They pass down-

wards and backwards from the sides of the lower margin of the soft palate, and each encloses a pharyngo-palatine muscle.

In the triangular interval which is formed by the divergence of the glosso- and pharyngo-palatine arches, on each side, lies a *palatine tonsil.*

Strictly speaking, the term *isthmus faucium* should be confined to the interval between the two glosso-palatine arches, as the palatine tonsil and the pharyngo-palatine arches belong to the side wall of the pharynx.

Pharynx.—The pharynx is a wide musculo-aponeurotic canal, about 12.5 cm. (5 inches) long. It extends from the base of the cranium to the level of the body of the sixth cervical vertebra (Fig. 110). There, at the lower border of the cricoid cartilage, it becomes continuous with the œsophagus. It is placed posterior to the nasal cavities, the mouth and the larynx, and it serves as the passage which conducts air to and from the larynx, as well as the food from the mouth to the œsophagus.

Under ordinary conditions it is expanded from side to side and compressed antero-posteriorly, so that it possesses anterior and posterior walls and two borders. Above the level of the orifice of the larynx there is always sufficient space for the passage of air to the lungs, but below the orifice of the larynx the anterior and posterior walls are in contact, except when separated by the passage of food (Fig. 112).

It is widest above, at the base of the cranium, posterior to the orifices of the auditory tubes (O.T. Eustachian). Thence it narrows to the level of the hyoid bone. It widens again at the level of the upper part of the larynx and then rapidly narrows to its termination.

To obtain a proper idea of the connections of the pharynx, the dissector should distend its walls moderately by stuffing it with tow. This may be introduced either from above, through the mouth, or from below, through the œsophagus.

When the pharynx is distended it has a somewhat ovoid form. *Posteriorly*, its wall is complete, and, when in position, it lies anterior to the upper six cervical vertebræ, the prevertebral muscles, and the prevertebral fascia. It is bound to the prevertebral fascia by some lax connective tissue which offers no impediment to the movements of the canal during the process of deglutition. *On each side*, the pharynx is related to the great vessels and nerves of the neck, as well

as to the styloid process and the muscles which take origin from it; and the pharyngeal plexus of nerves ramifies over its margin, extends on to its surfaces, and supplies it with motor and sensory twigs. *Anteriorly*, the pharyngeal wall is interrupted by the openings of the nasal cavities, mouth, and larynx; and it is from the structures which lie in proximity to those apertures that it derives its principal attachments. From above downwards it is attached, on each side—(*a*) to the medial pterygoid lamina; (*b*) to the pterygo-mandibular raphe; (*c*) to the side of the tongue; (*d*) to the medial aspect of the mandible; (*e*) to the hyoid bone; (*f*) to the thyreoid cartilage; (*g*) to the cricoid cartilage. *Above*, it is attached to the basis cranii. The various attachments will be studied more fully when the constituent parts of its walls are dissected.

It should be recognised that an altogether false idea of the natural form of the pharynx is obtained when it is removed from the vertebral column and is stuffed with tow or other substances. In transverse sections of the frozen body it will be noted that the cavity of the nasal part of the pharynx remains patent under all conditions, whilst at lower levels the anterior wall is more or less nearly approximated to the posterior wall, and below the opening of the larynx the cavity of the pharynx presents the appearance of a simple transverse slit.

Pharyngeal Wall.—The wall of the pharynx consists of four well-marked strata. From without inwards they are: (1) bucco-pharyngeal fascia; (2) pharyngeal muscles; (3) pharyngeal aponeurosis; (4) mucous membrane. The muscular layer, which is composed of the three constrictor muscles, with the stylo-pharyngeus and pharyngo-palatinus, on each side, must now be dissected.

Bucco-pharyngeal Fascia.—The bucco-pharyngeal fascia is a coating of fibrous tissue which covers both the buccinator and the pharyngeal muscles.

Dissection.—Remove the bucco-pharyngeal fascia and clean the pharyngeal muscles, sweeping the knife in the direction of their fibres. Note the veins which lie between the fascia and the muscles, forming the pharyngeal plexus, and the pharyngeal plexus of nerves to which the pharyngeal branches of the vagus nerve, the glosso-pharyngeal nerve, and the superior cervical sympathetic ganglion have already been traced. The veins and nerves must be removed for the proper display of the muscles.

Venæ Pharyngeæ.—The pharyngeal veins lie mostly upon the posterior wall and the borders of the pharynx, where they anastomose together in a plexiform manner. They constitute, collectively, the *pharyngeal venous plexus*, which receives blood from the pharynx, soft palate, and prevertebral region. It communicates with the pterygoid plexus and the cavernous

sinus. Two or more channels carry the blood from it to the internal jugular vein.

Constrictor Muscles.—The constrictor muscles are three pairs of curved sheets of muscular fibres which are so arranged that they overlap each other from below upwards; thus, the inferior constrictor overlaps the lower part of the middle constrictor, whilst the middle constrictor, in turn, overlaps the

lower part of the superior constrictor. The three muscles are inserted, in the median plane, into the median raphe which descends from the basilar portion of the occipital bone along the posterior aspect of the pharynx.

Musculus Constrictor Pharyngis Inferior (Fig. 107, *f*).—The inferior constrictor muscle is relatively short, anteriorly, at its origin, and relatively long, posteriorly, where it blends with the fellow of the opposite side in the median raphe of the posterior wall of the pharynx. It arises from the posterior part of the side of the cricoid cartilage, and from the inferior cornu, the oblique line, and the upper border of the thyreoid cartilage. The muscle curves backwards and medially, in the pharyngeal wall, to meet its fellow of the opposite side in the median raphe. The lower fibres take a horizontal direction, but the remainder ascend, with increasing degrees of obliquity, until the highest fibres reach the raphe at a point a short distance below the base of the skull. The lower margin of the inferior constrictor overlaps the commencement of the œsophagus, and the inferior laryngeal nerve and the laryngeal branch of the inferior thyreoid artery pass upwards, under cover of it, to reach the larynx. It is supplied by twigs from the pharyngeal plexus and the recurrent nerve.

Musculus Constrictor Pharyngis Medius.—The middle constrictor is a fan-shaped muscle (Fig. 107, *e*). It arises from the greater and lesser cornua of the hyoid bone and from the lower part of the stylo-hyoid ligament. From those origins its fibres pass round the pharyngeal wall, to be inserted with the corresponding fibres of the opposite side into the median raphe. As they curve backwards and medially, the lowest fibres descend, the highest ascend, and the intermediate fibres run horizontally. The lower portion of the muscle is overlapped by the inferior constrictor, and in the interval which separates the margins of the muscles anteriorly, opposite the thyreo-hyoid interval, the internal laryngeal nerve and the laryngeal branch of the superior thyreoid artery will be seen piercing the thyreo-hyoid membrane to gain the interior of the pharynx. It is supplied by twigs from the pharyngeal plexus.

***Dissection.*—To bring the extensive origin of the superior constrictor fully into view the internal pterygoid muscle must be cut through about its middle, if that has not been done already**

(p. 199), and then the upper and lower portions must be turned aside.

Musculus Constrictor Pharyngis Superior (Fig. 107, *d*).—The superior constrictor has a weak but continuous line of origin from the following parts: (*a*) the lower third of the posterior border of the medial pterygoid lamina and its hamulus; (*b*) the pterygo-mandibular raphe, which is common to it and the buccinator muscle; (*c*) the posterior end of the mylo-hyoid line on the medial aspect of the mandible; (*d*) the mucous membrane of the mouth and side of the tongue. From their origins, the fibres curve backwards and medially to reach the median raphe, whilst, as a rule, some of the highest gain a distinct insertion into the pharyngeal tubercle on the under surface of the basilar portion of the occipital bone.

The lower part of the superior constrictor is overlapped by the middle constrictor; and the stylo-pharyngeus passes into the interval between the two as it descends to its insertion (Fig. 107, *n*). The upper border of the muscle, which is free and crescentic, falls short of the base of the skull.

Raphe Pterygo-mandibularis (Fig. 107, *q*).—The pterygo-mandibular raphe is a strong, narrow, tendinous band, which extends from the hamulus of the medial pterygoid lamina to the posterior part of the mylo-hyoid line of the mandible. It acts as a tendinous bond of union between the buccinator and superior constrictor muscles. Its connections can be appreciated best by introducing the finger into the mouth and pressing laterally along the course of the raphe.

Sinus of Morgagni.—The term sinus of Morgagni is applied to the semilunar interval which intervenes between the basis cranii and the upper crescentic margin of the superior constrictor. The deficiency in the muscular wall of the pharynx in that region is compensated for by the increased strength of the pharyngeal aponeurosis, which, in that situation, is called the *pharyngo-basilar fascia*. In contact with the outer surface of the aponeurosis are two muscles belonging to the soft palate—viz. the *levator veli palatini* and the *tensor veli palatini* (Fig. 107, *c* and *b*). The levator, which is rounded and fleshy, lies posterior to the tensor, which is flat and more tendinous. The tensor can readily be recognised from its position in relation to the deep surface of the internal pterygoid muscle, and because its tendon turns medially under the hamulus of the medial pterygoid lamina. In the upper

part of the space, close to the base of the skull and between the origin of the two muscles, the *auditory tube* (O.T. *Eustachian tube*) can be defined.

Pharyngeal Aponeurosis.—The upper part of the pharyngeal aponeurosis is strong, and it maintains the integrity of the wall of the pharynx where the muscular fibres of the superior constrictor are absent. As it passes downwards it gradually becomes weaker, until it is ultimately lost as a distinct layer. It lies between the muscles and mucous membrane and is visible, from the outside of the pharynx, only where the muscles are absent. It is the principal means by which the pharynx is attached to the base of the skull, and it is united also to the auditory tubes and the bony margins of the *choanæ*.

Dissection.—The pharynx must now be opened by a vertical median incision through the entire length of its posterior wall. At the upper extremity of the cut, the knife should be carried transversely, close to the base of the skull. The stuffing must then be removed and the mucous surface of the pharynx cleansed.

Interior of the Pharynx.—The *mucous membrane* is now exposed, and it should be noted that it is continuous, through the various apertures which open into the pharynx, with the mucous membrane of the *nasal cavities*, the *auditory tubes* and *tympanic cavities*, the *mouth proper*, the *larynx*, and the *œsophagus*.

Racemose glands, which lie immediately subjacent to the mucous membrane and secrete mucus, are present in great numbers. There are also numerous *lymph follicles*, and in certain localities they are aggregated together into large masses (the palatine tonsils and the pharyngeal tonsil), which will be studied with the regions of the pharynx in which they are placed.

The soft palate projects into the pharynx, posterior to the isthmus faucium, and divides the cavity of the pharynx into an upper and a lower part. The *upper part*, called the *naso-pharynx*, communicates with the nasal cavities and the tympanic cavities by four apertures, viz. the two choanæ (O.T. posterior nares) and the two auditory tubes (O.T. Eustachian tubes).

The *lower portion* of the pharynx may be regarded as consisting of an *oral part*, which lies posterior to the mouth and tongue, and a *laryngeal part*, placed posterior

to the larynx. Below the soft palate there are three openings into the pharynx, viz. the *opening of the mouth* or *isthmus faucium*, the *opening of the larynx*, and the *opening of the œsophagus.*

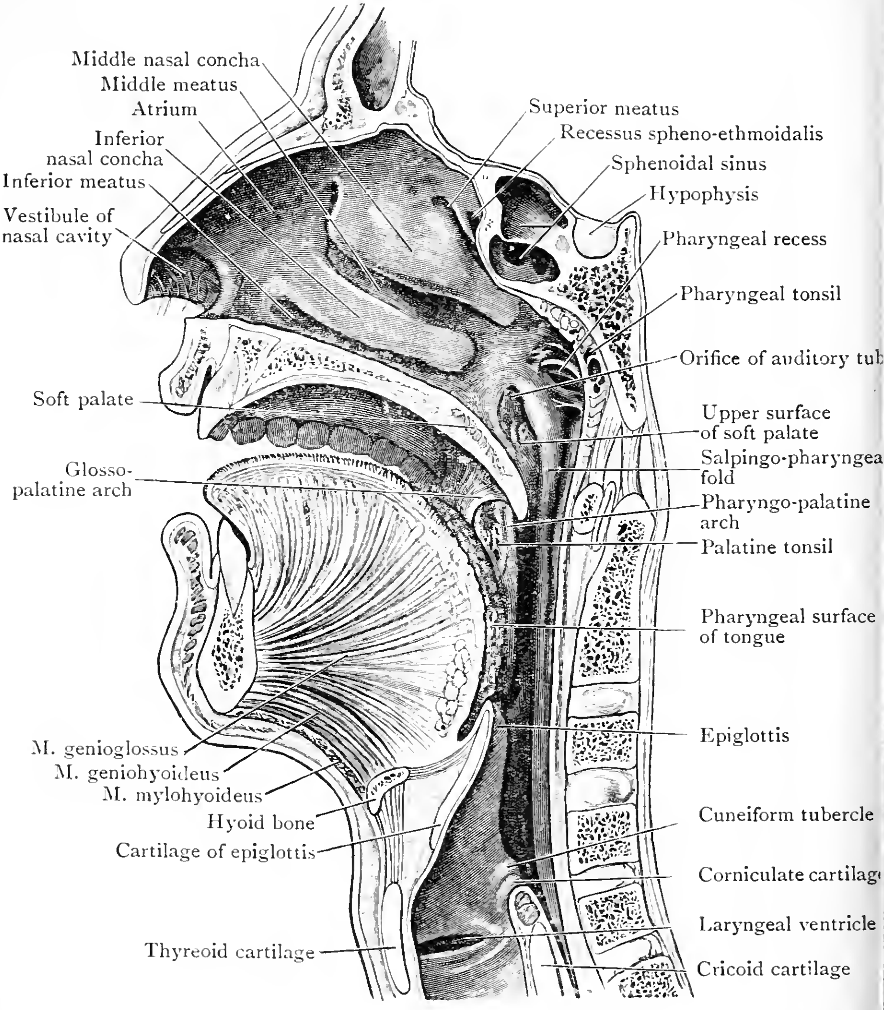

FIG. 110.—Sagittal section, a little to the right of the median plane, through the Nasal Cavity, the Mouth, Pharynx, and Larynx.

Pars Nasalis.—The naso-pharynx is situated immediately posterior to the nasal cavities and below the body of the sphenoid and the basilar part of the occipital bone. It is the widest part of the pharynx. Its walls, except the soft palate, are not capable of movement, and, consequently, its cavity

lways remains patent, and presents under all conditions very nuch the same form.

In its *anterior boundary* are the choanæ, through which it pens into the nasal cavities. The *choanæ* are two oblong rifices which slope from the base of the cranium downwards nd forwards to the posterior border of the hard palate. Each is about 25 mm. (one inch) long and 12.5 mm. (half an nch) wide, and it is separated from its fellow by the posterior art of the septum nasi, which is formed by the posterior order of the vomer. By looking through the choanæ the lissector will obtain a partial view of the lower two meatuses f the nose and of the posterior ends of the middle and nferior conchæ.

On each *side wall* of the naso-pharynx is seen the orifice f the corresponding auditory tube, and posterior to it the haryngeal recess. The *pharyngeal orifice* of the auditory ube lies immediately posterior to the lower part of the orresponding choana, on a level with the posterior end of he inferior concha of the same side. It is bounded above nd posteriorly by a prominent and rounded margin termed he *torus tubarius*, which is altogether deficient below and nteriorly. A fold of mucous membrane, termed the *salpingo-haryngeal fold*, descends, upon the side wall of the pharynx, rom the posterior lip of the orifice of the auditory tube. As he fold is traced downwards it gradually disappears.

The dissector should pass a Eustachian catheter through the nose into he auditory tube. Hold the catheter with the point downwards. Pass it ackwards through the right nasal cavity, along the septum of the nose, to he posterior wall of the pharynx. Pull it towards the palate till the bent end f the catheter catches against the back of the hard palate. Turn the point hrough a quarter of a circle to the right side of the head and it will enter he right auditory tube. If it is desired to catheterise the left auditory tube ass the catheter through the left nasal cavity, and in the final stage turn the oint to the left side.

In the natural condition of parts there is a deep recess n the side wall of the naso-pharynx immediately posterior o the prominent posterior lip of the orifice of the auditory ube. It is termed the *pharyngeal recess*.

The *roof* and *posterior wall* of the naso-pharynx are not narked off from one another. They form together a continuous urved surface. The upper portion of the surface looks lownwards and may be regarded as the roof; the lower portion, which looks forwards, constitutes the posterior wall. The *roof*

is formed by the basilar part of the occipital bone, and also by a small part of the under surface of the basi-sphenoid, both of which are covered with a dense periosteum and a thick coating of mucous membrane. The *posterior wall* is supported, *posteriorly*, by the anterior arch of the atlas and the anterior surface of the epistropheus. In that part of the roof which lies between the two pharyngeal recesses there is a marked collection of lymphoid tissue, called the *pharyngeal tonsil*. Over its surface the mucous membrane is thickened and wrinkled, and in its lower part a small median pit, termed the *pharyngeal bursa*, may sometimes be found; the bursa is just large enough to admit the point of a fine probe.

The *floor* of the naso-pharynx is formed by the curved, sloping upper surface of the soft palate. Between the posterior border of the soft palate and the posterior wall of the pharynx there is an interval, termed the *naso-pharyngeal isthmus*, through which the naso-pharynx communicates with the oral pharynx.

It is important to note that the posterior wall and roof of the naso-pharynx can be explored by the finger introduced through the mouth and the naso-pharyngeal isthmus.

When the naso-pharynx is illuminated, by light reflected from a mirror introduced through the mouth, a view of the four orifices which open into the nasal part of the pharynx may be obtained. Owing to the mirror being placed obliquely, and below the level of the hard palate, only the posterior parts of the inferior conchæ are visible through the choanæ, and the inferior meatuses of the nose are altogether out of sight. The middle and superior meatuses of the nose and the middle and superior conchæ, however, can be brought into view and their condition ascertained. The lateral walls of the naso-pharynx and the orifices of the auditory tubes also can be fully inspected.

Pars Oralis.—The oral pharynx lies posterior to the mouth and tongue. The *anterior wall* of its lower part is formed by the base or pharyngeal part of the tongue, which looks more or less directly backwards. Above the tongue is the isthmus of the fauces, or the opening into the mouth, limited on each side by the glosso-palatine arch. The glosso-palatine arches may be regarded, therefore, as the lateral boundary lines between the mouth and the pharynx. On the *side wall* of the oral pharynx the pharyngo-palatine arch forms a prominent fold which gradually disappears as it passes back-

wards and downwards. Within the fold is the pharyngo-palatine muscle, which is of importance because the posterior palatine arches form the boundaries of the naso-pharyngeal isthmus, on each side, and by the contraction of the pharyngo-palatine muscles the two pharyngo-palatine arches can be approximated until the opening of the isthmus is obliterated; the passage of food and fluids from the oral pharynx into the naso-pharynx is thus prevented.

The glosso-palatine arch and the pharyngo-palatine arch form, on each side-wall of the oral pharynx, the anterior and posterior limits of a triangular interval in which is lodged the palatine tonsil. The upper part of the interval, above the level of the tonsil, forms a small depression termed the *supra-tonsillar fossa.*

In the child, and not uncommonly in the adult, a triangular fold of mucous membrane, called the *plica triangularis*, extends backwards from the lower part of the glosso-palatine arch and the base of the tongue across the surface of the palatine tonsil. The upper border of the fold may be free or it may become attached to a greater or less extent to the surface of the tonsil.

Pars Laryngea.—The laryngeal portion of the pharyngeal cavity diminishes rapidly in width to the level at which it becomes continuous with the œsophagus. In its anterior wall, from above downwards, may be seen: (1) the epiglottis; (2) the superior aperture of the larynx, with a recessus piriformis on each side; and (3) the posterior surfaces of the arytænoid and cricoid cartilages, covered with muscles and mucous membrane.

Aditus Laryngis.—The *superior aperture of the larynx*, situated below the pharyngeal part of the tongue, is a large, obliquely placed opening which slopes rapidly from above downwards and backwards. It is somewhat triangular in outline. The basal part of the opening, placed above and anteriorly, is formed by the free border of the epiglottis. Posteriorly, the opening rapidly narrows, and it ends in the interval between the two arytænoid cartilages. The sides of the aperture are formed by two sharp and prominent folds of mucous membrane, termed the *ary-epiglottic folds*, which connect the right and left margins of the epiglottis with the corresponding arytænoid cartilages. Two small nodules of cartilage, in the posterior part of each ary-epiglottic fold,

produce two rounded eminences, of which the anterior is the *cuneiform tubercle*, and the posterior is the *corniculate tubercle.*

On each side of the lower part of the laryngeal opening there is a small three-sided or pyramidal depression, called the *recessus piriformis.* On the lateral side each piriform recess is bounded by the posterior part of the corresponding lamina of the thyreoid cartilage and the corresponding part of the thyreo-hyoid membrane; on the medial side, by the arytænoid

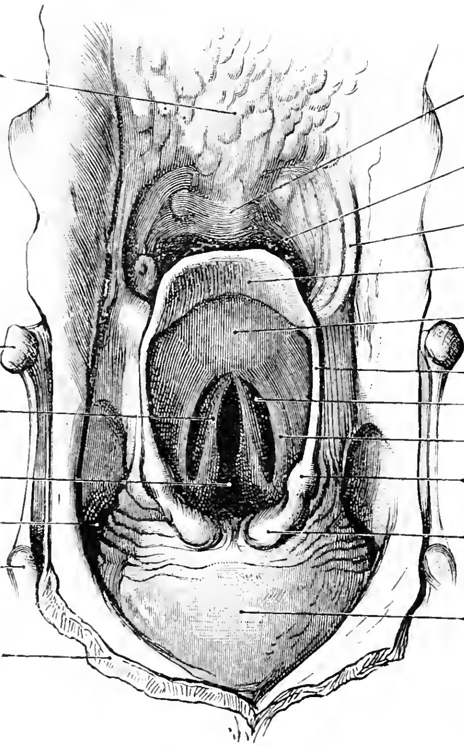

FIG. 111.—Superior Aperture of Larynx exposed by cutting through the posterior wall of the pharynx.

cartilage and the ary-epiglottic fold; whilst its posterior wall is formed by the posterior wall of the pharynx, when that is in place. The piriform recess has a wide entrance, which looks upwards; but it rapidly narrows towards the bottom (Figs. 111 and 112). It is of practical importance because sharp-pointed bodies introduced into the pharynx are liable to be caught in the walls of the sinus.

Below the level of the opening of the larynx, the anterior

and posterior walls of the pharynx are always closely applied to each other, except during the passage of food.

The *œsophageal opening* is placed opposite the lower border of the cricoid cartilage, at the narrowest part of the pharynx.

Velum Palatinum.—The soft palate is a movable curtain, which projects downwards and backwards into the pharynx. During deglutition it is raised, and helps to shut off the nasal part of the pharynx from the portion below. *Anteriorly*, it is attached to the posterior margin of the hard palate; *on each side* it is connected with the side wall of the pharynx; whilst *posteriorly* it presents a free border. From the centre

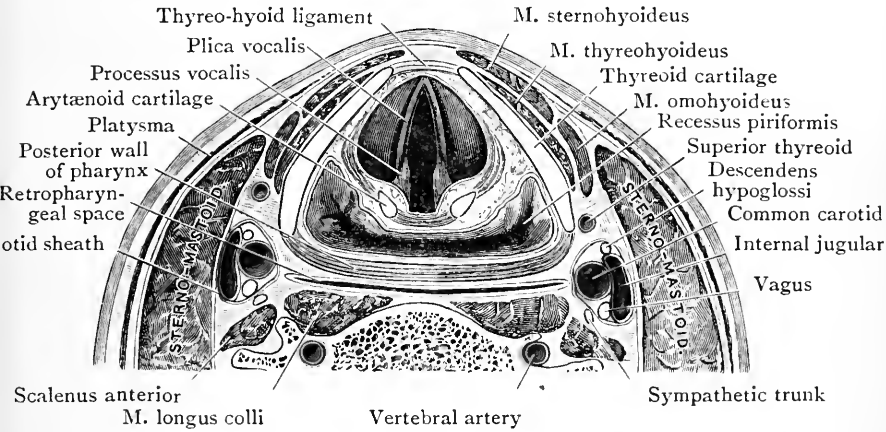

FIG. 112.—Transverse section through the Neck at the level of upper part of the Thyreoid Cartilage.

of the free margin the conical process, termed the *uvula*, projects; whilst the sharp concave part of the border, on each side of the uvula, becomes continuous with the pharyngopalatine arch, which descends on the side-wall of the pharynx. The *upper surface* of the soft palate is convex and continuous with the floor of the nasal cavities. The *inferior surface* is concave and forms part of the vaulted roof of the mouth and the roofs of the supra-tonsillar recesses. From the posterior part of the inferior surface, on each side, a glossopalatine arch curves downwards; and along its median plane may be seen a slightly marked median ridge or raphe.

The soft palate is composed of a fold of mucous membrane, between the two layers of which are interposed muscular,

aponeurotic, and glandular structures, together with blood vessels and nerves.

Nerves, . .
- Middle palatine, Posterior palatine, } from the spheno-palatine ganglion.
- Branches from pharyngeal plexus.

The *racemose mucous glands* in the soft palate form a very thick layer, immediately subjacent to the mucous membrane which clothes its inferior surface. Close to the posterior border of the hard palate the soft palate contains very few muscular fibres; and in that situation it is composed chiefly of the two layers of mucous membrane enclosing the glands and the palatal aponeurosis.

Dissection.—The dissection of the soft palate is difficult, and it is only in a fresh part that the precise relations of the different muscular layers can be made out. Begin by rendering it tense by means of a hook, and then carefully remove the mucous membrane from its upper and lower surfaces, and also from the glosso- and pharyngo-palatine arches. The latter proceeding will expose the glosso-palatine and the pharyngo-palatine muscles, on each side.

Musculi Glosso-palatini.—The glosso-palatini are delicate muscular slips, each of which arises from the side of the posterior part of the tongue, whence it curves upwards and medially to reach the under surface of the soft palate, above the glandular layer. There its fibres spread out and become continuous with the corresponding muscular fasciculi of the opposite side. It forms the lowest muscular stratum of the soft palate. The nerve supply is derived from the accessory nerve. When the glosso-palatini muscles contract the glosso-palatine arches are approximated in the median plane, and the cavity of the mouth is shut off from the cavity of the pharynx.

Musculi Pharyngo-palatini.—In the soft palate each pharyngo-palatine muscle consists of two strata, an upper

and a lower, between which are enclosed the corresponding muscle of the uvula and the levator of the soft palate.

The *upper layer* is very weak and confined to the posterior part of the velum. It constitutes the most superficial muscular stratum on the upper aspect of the soft palate, and becomes continuous with the corresponding portion of the muscle of the opposite side. The *deeper layer* takes origin from the posterior margin of the palate bone and from the palatal aponeurosis, and some of its fibres mingle with those of the corresponding muscle of the opposite side. Lateral to the soft palate the two strata blend, and are joined by one or two delicate muscular slips which spring from the lower border of the cartilage of the auditory tube. Those slips are sometimes described as the *salpingo-pharyngeus muscle*. The three parts blend at the postero-lateral border of the soft palate, and from there the pharyngo-palatinus passes downwards and backwards in the pharyngo-palatine arch, and spreads out into a thin sheet of fibres in the wall of the pharynx. The pharyngo-palatinus blends, to some extent, with the stylo-pharyngeus, and is inserted, with the stylo-pharyngeus, into the posterior border of the thyreoid cartilage. Some of its fibres, however, incline backwards and are inserted into the pharyngeal aponeurosis. It helps to close the isthmus of the pharynx and to elevate the larynx; it is supplied by the accessory nerve.

Musculi Uvulæ.—The two small muscles of the uvula, right and left, lie in the upper part of the soft palate, covered on their upper surfaces by the upper parts of the pharyngo-palatine muscles, which must be removed before the muscles of the uvula can be seen. Each muscle of the uvula is a minute slip which springs from the posterior nasal spine. As they pass backwards the two slips blend, and their fibres are inserted into the mucous membrane of the uvula. They are supplied by the accessory nerve, and when they contract they elevate the uvula.

Dissection.—The levator veli palatini muscle has been seen already, on the outer aspect of the pharynx, in the sinus of Morgagni (Fig. 107). To display it from the inside it is necessary to remove the mucous membrane, the submucous tissue, and the membranous part of the wall of the pharynx between the auditory tube, above, and the upper border of the superior constrictor, below; afterwards the fibres of the muscle must be followed into the soft palate where it lies between the two layers of the pharyngo-palatine muscle. In a well-injected subject the dissector

will note the terminal part of the ascending palatine branch of the external maxillary artery descending along the levator palati into the soft palate.

Musculi Levatores Veli Palatini.—Each elevator muscle of the soft palate is a rounded, fleshy muscle which arises from the lower and medial border of the cartilage of the corresponding auditory tube, and from the rough surface on the under aspect of the apex of the petrous part of the adjacent temporal bone. It passes downwards and forwards, crosses the upper border of the superior constrictor, pierces the pharyngeal aponeurosis, passes below the orifice of the auditory tube, and enters the soft palate. There its fibres spread out below the uvular muscle and above the anterior or deep portion of the pharyngo-palatinus. Anteriorly, some of the fibres are inserted into the palatal aponeurosis; but more posteriorly, the majority of the fibres become continuous with the corresponding fasciculi of the opposite side. The nerve supply is derived from the accessory nerve. The name of the muscle indicates its action.

Musculi Tensores Veli Palatini.—The origin of each tensor muscle of the soft palate and the relations of its muscular belly were noted on p. 200. The muscle descends from the scaphoid fossa of the base of the skull along the lateral surface of the medial pterygoid lamina, and it ends in a tendon which turns horizontally towards the median plane, below the hamulus, where a bursa mucosa facilitates the play of the tendon on the bone. In the soft palate the tendon expands below the lower layer of the pharyngo-palatinus, and some of its fibres blend with the palatal aponeurosis, whilst others gain attachment to the horizontal part of the palate bone. It is supplied by the mandibular division of the trigeminal nerve. Its name indicates its action.

Palatal Aponeurosis.—The palatal aponeurosis extends backwards from the posterior margin of the hard palate, to give strength and support to the soft palate. At first it is strongly marked, but it weakens rapidly as it passes posteriorly. The small portion of the soft palate which it supports contains few muscular fibres, and remains always more or less horizontal in position. The much more extensive posterior muscular part of the soft palate constitutes the movable sloping portion. The tensor of the soft palate

operates upon the anterior aponeurotic portion of the soft palate.

Vessels and Nerves of the Soft Palate.—The *ascending palatine branch* of the external maxillary artery is, as a rule, the principal artery of supply to the soft palate. It has already been traced on the wall of the pharynx (pp. 205 and 210), where it lies in the sinus of Morgagni, in relation to the levator veli palatini muscle, which it accompanies into the soft palate. The *palatine branch* of the ascending pharyngeal artery may also be traced into the soft palate; in cases where the ascending palatine artery is small, this twig becomes enlarged and takes its place (p. 210). The *descending palatine branch* of the internal maxillary artery also sends small twigs to the soft palate and palatine tonsil.

Two nerves enter the soft palate from the spheno-palatine ganglion—viz., the *posterior palatine* and the *middle palatine nerve.* It would appear, however, that they do not supply the muscles, but are distributed to the mucous membrane. The levator veli palatini, the musculus uvulæ, the glosso-palatinus, and the pharyngo-palatinus are supplied by twigs from the pharyngeal branches of the vagus, which convey to the muscles fibres which are originally derived from the cerebral part of the accessory nerve (*v.* p. 223) (W. Aldren Turner). The tensor veli palatini is probably supplied by the branch which it receives from the otic ganglion, which conveys to it fibres originally derived from the motor part of the mandibular division of the trigeminal nerve.

Tonsillæ Palatinæ.—The palatine tonsils are two prominent masses of lymphoid tissue, placed one in each side wall of the pharynx, in the triangular interval between the two palatine arches and immediately above the pharyngeal part of the tongue. The *pharyngeal* or *medial surface* of the tonsil is covered with mucous membrane and presents a number of orifices which lead into crypts or recesses in its substance. The *deep* or *lateral surface* is embedded in the pharyngeal wall and is supported by the superior constrictor muscle of the pharynx (see p. 205). It is covered by a layer of fibrous tissue which forms an incomplete capsule for the organ. It is important to note that between the palatine tonsil and the superior constrictor there is some lax connective tissue, so that the tonsil can be pulled forwards by the vol-sellum without dragging the wall of the pharynx with it.

Each palatine tonsil has a rich *blood-supply*. It derives arterial twigs from the tonsillar and ascending palatine branches of the external maxillary, the descending palatine branch of the internal maxillary, the ascending pharyngeal, and the dorsalis linguæ of the corresponding side.

The dissectors should note that the tonsil lies at about the level of the angle of the mandible, and that the wall of the pharynx separates it from the external maxillary artery. The internal and external carotid arteries also lie lateral to the region of the tonsil, but they are further away than the external maxillary.

Tuba Auditiva (O.T. **Eustachian Tube**).—The auditory tube is the canal which conveys air from the pharynx to the tympanic cavity. It is about 25 mm. long and is divided into two portions, according to the parts which enter into the construction of its wall. In the *lateral part* of its course, as it nears the tympanic cavity, its walls are bony, and it runs in the interval between the tympanic and petrous portions of the temporal bone. The *medial part* consists mainly of cartilage. It is placed on the base of the skull, and is lodged in the gutter or groove between the petrous part of the temporal bone and the great wing of the sphenoid. The cartilaginous part of the tube comes under the notice of the dissector at the present stage, and he should first note its direction and then study its relations and the construction of its wall.

The dissector can readily ascertain the direction of the canal by passing a probe into it through its pharyngeal orifice. It runs backwards and laterally, with a slight inclination upwards, and passes first above and then to the lateral side of the elevator muscle of the soft palate, and along the medial side of the upper part of the tensor of the soft palate. It lies, therefore, in a considerable part of its extent, between the two muscles (Fig. 218).

Before removing the mucous membrane from the pharyngeal part of the tube, the dissector should note that at the lower margin of the orifice there is a prominent rounded eminence, the *levator cushion*, due to the subjacent elevator muscle of the soft palate. The removal of the mucous membrane will reveal the fact that the wall of the tube is formed, in great part, by a triangular plate of cartilage, which is folded upon itself so as to protect the tube on its upper and

medial aspects. The cartilage is deficient below and laterally, its place being taken by dense fibrous tissue, which connects the margins of the cartilage and completes the wall of the canal. The projecting free base of the cartilage gives rise to the torus tubarius, already examined, on the side wall of the naso-pharynx (p. 289). A muscular slip, which descends from the lateral margin of the cartilage, in relation to the lateral, unprotected side of the tube, has been termed the *dilatator tubæ* (Rudinger). It joins the tensor of the soft palate. The interior of the tube is lined with mucous membrane continuous with that of the pharynx and the tympanic cavity; and its calibre varies considerably in different parts of its course. It is narrowest at a point termed the *isthmus*, situated at the junction of the osseous and cartilaginous parts. As the tube is traced from the isthmus to the pharynx it gradually increases in calibre, and it attains its greatest width at its pharyngeal aperture.

CAROTID CANAL.

The carotid canal, which traverses the petrous part of the temporal bone, contains the internal carotid artery, the internal carotid continuation of the cervical part of the sympathetic trunk, and a plexus of veins.

Dissection.—To open up the carotid canal, remove its inferior wall with the bone forceps; but do not interfere with the auditory tube, which lies in close proximity. The dissection must be made on one side only.

Arteria Carotis Interna.—The portion of the internal carotid artery which passes through the carotid canal in the petrous part of the temporal bone is about 18 mm. (three-quarters of an inch) long. At first it ascends vertically; then, bending suddenly, it runs horizontally and forwards. It emerges from the canal at the apex of the petrous bone and enters the foramen lacerum, where it turns upwards, pierces the external layer of the dura mater, and enters the middle fossa of the skull. The remainder of the course of the internal carotid artery has been examined already (p. 239). Within the carotid canal it lies below and anterior to the cochlea and the tympanic cavity. The greater superficial petrosal nerve and the semilunar ganglion are placed

above it, but are separated from it by a thin plate of bone, which, however, may be replaced by fibrous tissue.

Nervus Caroticus Internus.—The dissector has already noted that the internal carotid nerve is a large branch which proceeds from the upper end of the superior cervical ganglion, and enters the carotid canal, with the internal carotid artery. It divides almost immediately into two parts, which are placed one on each side of the artery. Each part soon divides into a number of branches which communicate together, around the internal carotid artery, forming the *internal carotid plexus*. The dissection of the branches is a matter of some difficulty, and can be satisfactorily effected only under specially favourable circumstances.

At the posterior end of the cavernous sinus a ganglion is sometimes found in the plexus, and where the sixth nerve crosses the internal carotid artery the plexus is very dense. That part is known as the *cavernous plexus*. At the anterior end of the cavernous sinus the carotid plexus breaks up into branches which accompany the anterior and middle cerebral arteries.

The internal carotid plexus communicates with the tympanic plexus by means of superior and inferior carotico-tympanic branches given off in the carotid canal, and with the spheno-palatine ganglion by the great deep petrosal branch, which unites with the greater superficial petrosal of the facial nerve to form the nerve of the pterygoid canal (O.T. Vidian). It gives branches also to the semilunar ganglion, the third, fourth, sixth and the ophthalmic branch of the fifth nerve, and a branch which accompanies the naso-ciliary nerve into the orbit, where it joins the ciliary ganglion.

NERVUS MAXILLARIS.

As the maxillary nerve passes forwards, from the semilunar ganglion to the face, it traverses the foramen rotundum, the upper part of the pterygo-palatine fossa, the pterygo-maxillary fissure, the infra-temporal fossa, the inferior orbital fissure, and the infra-orbital canal. The dissector should therefore proceed to expose the nerve in those localities.

Dissection.—Remove the temporal muscle and the upper head of the external pterygoid muscle, and, placing the saw

upon the cut margin of the skull at a point immediately above the external meatus, carry it obliquely downwards and forwards, through the squamous part of the temporal bone and the great wing of the sphenoid, towards the medial end of the superior orbital fissure. This saw-cut should enter the superior orbital fissure immediately to the lateral side of the foramen rotundum. A second saw-cut should then be made from the cut margin of the cranial wall, immediately above the anterior margin of the great wing of the sphenoid bone, downwards into the superior orbital fissure to meet the first saw-cut. The wedge-shaped piece of bone included between the cuts can now be removed. To obtain additional space, and to open up the pterygo-palatine fossa more fully, remove what remains of the great wing of the

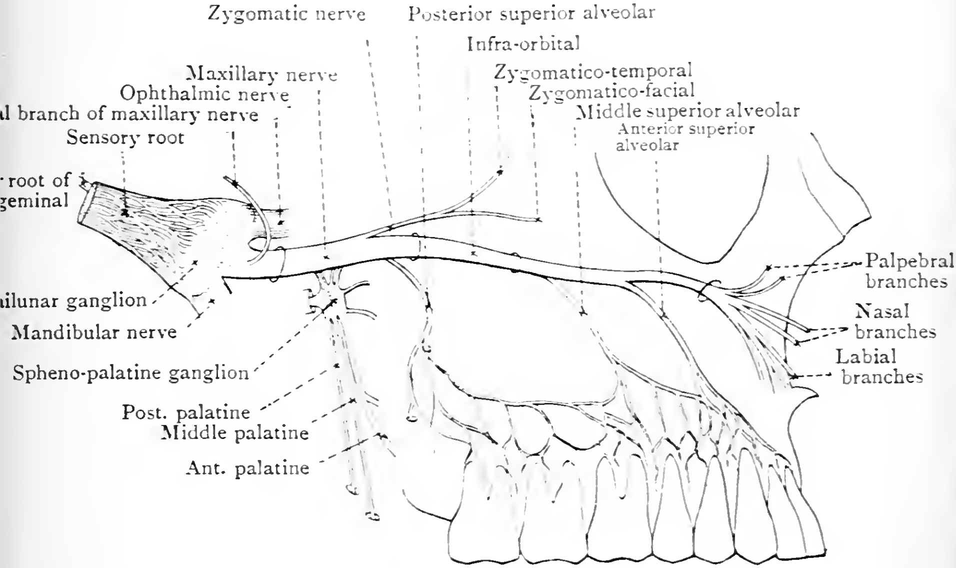

FIG. 113.—Diagram of the Maxillary Nerve.

sphenoid upon the lateral side of the foramen rotundum, but the circumference of that aperture must be carefully preserved. Proceed, in the next place, to open up the infra-orbital canal. In its posterior part its upper wall is usually so thin that it can easily be removed by a pair of dissecting forceps, but more anteriorly the canal sinks deeply under the lower part of the rim of the orbital opening, and there the chisel must be employed. The maxillary nerve can now be defined and its branches displayed. The infra-orbital artery and vein, which accompany the nerve in the infra-orbital canal, will be exposed at the same time.

Nervus Maxillaris.—The maxillary nerve springs from the semilunar ganglion, within the cranial cavity (Fig. 113). It is composed entirely of sensory fibres, and passes forwards, outside the dura mater and in relation to the lower part of the

cavernous sinus, to the foramen rotundum, through which it enters the pterygo-palatine fossa. It crosses the upper part of that fossa, curves laterally through the pterygo-maxillary fissure into the infra-temporal fossa, and, near the middle of the inferior orbital fissure, enters the infra-orbital canal, where it receives the name of *infra-orbital*. The infra-orbital canal traverses the floor of the orbit, which, it should be remembered, forms the roof of the maxillary sinus also. Finally, leaving the infra-orbital canal, the nerve emerges upon the face through the infra-orbital foramen, and breaks up, under cover of the quadratus labii superioris, into numerous branches which unite with twigs from the facial nerve to form a dense plexus. Its terminal filaments are distributed to the lower eyelid, the nose, and the upper lip. The course of the maxillary nerve may be separated into five stages, in each of which branches are given off. These are:—

1. Within the cranium, .	Meningeal (p. 238).	
2. In the pterygo-palatine fossa, . .	Spheno-palatine.	
3. In the infra-temporal fossa, . . .	Zygomatic (already described, p. 261). Posterior superior alveolar.	
4. In the infra-orbital canal, . . .	Middle superior alveolar. Anterior superior alveolar.	
5. In the face, . .	Palpebral, Nasal, Labial,	already described: (p. 15).

The *spheno-palatine branches* are two stout twigs which arise from the inferior aspect of the maxillary nerve, and proceed vertically downwards, in the pterygo-palatine fossa, to the spheno-palatine ganglion, of which they constitute the *sensory roots*.

The *zygomatic nerve*, which has already been dissected in the orbit, can now be traced to its origin from the maxillary nerve in the infra-temporal fossa.

Nervi Alveolares Superiores.—There are usually three superior alveolar nerves which are distinguished as posterior, middle, and anterior. The middle superior alveolar nerve is sometimes absent as a separate trunk, in which case its fibres arise in common with the anterior superior alveolar branch.

The *posterior superior alveolar nerve* takes origin in the infra-temporal fossa, and almost immediately divides into two branches, which proceed downwards upon the posterior

aspect of the body of the maxilla. They contribute a few fine filaments to the mucous membrane of the cheek and to the gum, and then disappear into the minute posterior alveolar foramina to supply the three molar teeth and the lining membrane of the maxillary sinus.

The *middle superior alveolar nerve* supplies the two premolar teeth. It arises from the infra-orbital nerve, and can be easily detected (if present as a separate branch) when the parent trunk is gently raised from the floor of the infra-orbital canal. It descends in a minute canal which traverses the lateral wall of the maxillary sinus.

The *anterior superior alveolar nerve*, much the largest of the three alveolar branches, springs from the infra-orbital as it approaches the anterior part of the canal. To bring it into view raise the parent trunk from the floor of the canal, and the branch will then be seen to enter a special bony tunnel which traverses the maxilla in the anterior wall of the maxillary sinus. The dissector should endeavour to open up that canal with the chisel. After supplying a branch to the mucous membrane of the lower and anterior part of the nasal cavity, the anterior superior alveolar nerve divides into branches for the incisor and the canine teeth.

While traversing the maxilla, the three superior alveolar branches communicate with one another, and form two nerve loops (Fig. 113). Numerous twigs proceed from both loops, and they communicate with one another to form a fine plexus. It is from that plexus that the terminal filaments to the teeth and gums take origin.

Arteria Infraorbitalis.—The infra-orbital artery is a branch of the internal·maxillary. It arises in the pterygo-palatine fossa and accompanies the infra-orbital nerve. In the face its terminal twigs anastomose with branches of the external maxillary, transverse facial, and buccinator arteries; in the infra-orbital canal it gives some fine branches to the contents of the orbital cavity, and also the *anterior superior alveolar artery* which accompanies the nerve of that name, and supplies the incisor and canine teeth, and the lining membrane of the maxillary sinus.

The *infra-orbital vein* joins the pterygoid plexus.

NASAL CAVITIES.

Dissection.—The portion of the mandible which still remains, together with the tongue and larynx, must now be removed from the upper part of the skull. From the angle of the mouth, on each side, carry the knife backwards, through the buccinator and the mucous membrane of the cheek, and through the pterygo-mandibular raphe and the side wall of the pharynx. The internal pterygoid muscle has been divided already, but it will be necessary to cut the internal carotid artery, the smaller vessels which are still undivided and the nerves which still connect the pharynx with the skull. The larynx and tongue must be laid aside for future dissection.

The anterior part of the skull should next be divided into two parts by sawing through it, in the sagittal direction, close to one side of the nasal septum. As a general rule the nasal septum is not vertical, but deviates more or less to one or other side of the median plane. The deviation is more frequently to the right than to the left side. Endeavour to determine the direction which it takes in the skull under observation by passing a probe into the nasal cavity through the choanæ. The section through the skull should be made close to the concave side of the septum. Begin anteriorly by introducing a knife into the nostril of that side, and carry it upwards through the cartilaginous part of the nose to the nasal bone. Then place the specimen so that the face rests upon the table, and divide the soft palate in the median plane. The section may now be completed by sawing through the hard palate and bony roof of the nasal cavity at the side of the median plane. The dissector should make every effort to preserve the septum of the nose intact. As a general rule the upper concha is partially injured. That is not a very serious matter, as the lateral aspect of the nasal cavity can be studied upon the opposite side when the septum of the nose has been removed.

Septum Nasi.—The nasal septum divides the cavity of the nose into two narrow chambers—the right and left nasal cavities. It is not placed accurately in the median plane, but almost invariably shows a bulging or deviation to one or other side (more frequently to the right side). Immediately above the orifice of the nostril or anterior aperture of the nasal cavity, the septum shows a slight depression which corresponds to the *vestibule* of the nose, and forms the medial wall of that subdivision of the nasal cavity. The vestibular part of the partition is clothed with skin, continuous with the external integument; a number of stiff hairs, termed *vibrissæ*, project from the skin into the cavity. Over the rest of its extent the septum nasi is covered with mucous membrane, which is closely adherent to the subjacent periosteum forming with it a *muco-periosteum*; and it is

separable into two districts, viz., a lower or *respiratory area*, and a much smaller upper or *olfactory area*, comprising not more than the upper third of the septum, in which branches of the olfactory nerve spread out. The respiratory mucous membrane is very thick and spongy. It is highly vascular and contains numerous mucous glands. The minute orifices of the gland ducts can be detected by the naked eye. Over the olfactory district of the septum the mucous

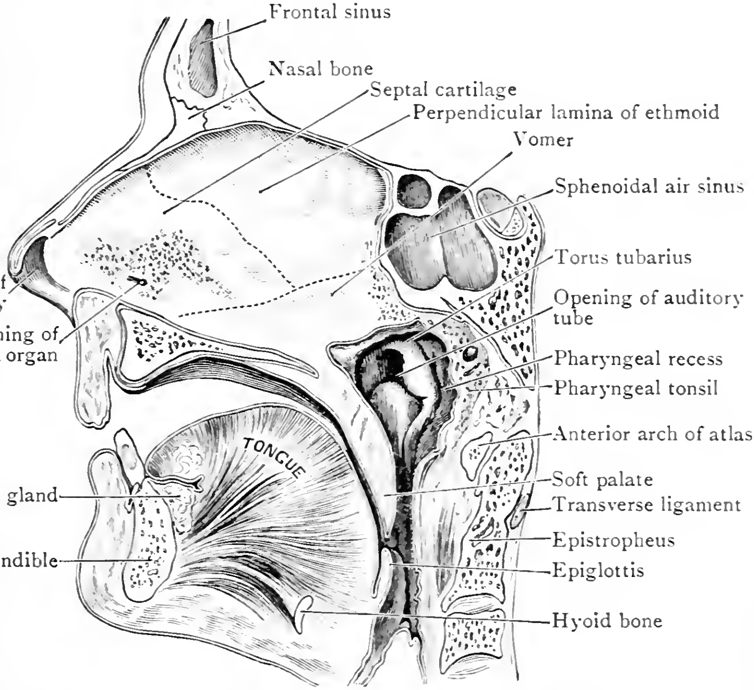

FIG. 114.—Antero-posterior section through the Nose, Mouth, and Pharynx, a little to the left of the median plane.

membrane is softer and more delicate, and not so thick. In the fresh state it presents a yellowish colour, and the glands are smaller.

In favourable cases a minute orifice may be detected in the mucous membrane on the lower and anterior part of the nasal septum, immediately posterior to the vestibular area. It is placed above the anterior end of a well-marked elongated projection which passes obliquely backwards and upwards, and corresponds to the thickened lower margin of the septal cartilage. The aperture varies in diameter from $\frac{1}{2}$ mm. to $1\frac{1}{2}$ mm. (Schwalbe). It leads into a narrow canal, which passes backwards for a short distance, and then ends blindly. It is of interest because it represents in the human subject the rudiment of the *vomero-nasal organ*

(O.T. *organ of Jacobson*), a tubular structure which is highly developed in some of the lower animals.

Construction of the Nasal Septum.—Strip the muco-periosteum from the exposed surface of the septum nasi, and the parts forming the septum will be rendered visible. The bulk of the partition is composed of the vomer and the perpendicular lamina of the ethmoid posteriorly, and of the septal cartilage anteriorly. Small portions of other bones take a minor part in its construction. Thus, above and posteriorly there are the crest and rostrum of the sphenoid; above and anteriorly are the nasal spine of the frontal bone and the crest of the nasal bones; whilst below there is the crest of bone formed by the apposition of the palatal processes of the palate and maxillary bones of opposite sides.

Cartilago Septi Nasi.—The septal cartilage fills up the wide angular gap which intervenes between the vomer and the perpendicular lamina of the ethmoid, and it projects forwards towards the point of the nose. It is a broad irregularly quadrilateral plate. Its *upper and posterior border* is in apposition with the anterior border of the perpendicular lamina of the ethmoid; *its lower and posterior border*, much thickened, is received into the groove in the anterior border of the vomer and the nasal crest of the maxillæ. The angle between the two borders mentioned is prolonged backwards, for a varying distance, in the form of a tongue-shaped cartilaginous process, which occupies the interval between the two plates of the vomer. The *upper and anterior border* of the septal cartilage is in contact, above, with the suture between the two nasal bones; below that, it is related to the two lateral cartilages of the nose, whilst still lower down it occupies the interval between the medial parts of the two larger alar cartilages.

Its connection with the lateral cartilage on each side is a very intimate one; indeed, below the nasal bones, the three cartilages are directly continuous, but lower down they are separated by a fissure which runs upwards for some distance on each side. The *lower and anterior border* is very short; it is free, and extends backwards to the anterior nasal spine. The anterior angle of the septal cartilage is blunt and rounded, and does not reach to the point of the nose, which is formed by the alar cartilages.

The deviation of the septum nasi from the median plane will now (in all probability) be seen to be due to a bulging of the vomer and perpendicular lamina of the ethmoid to one side, along their line of union. It is not developed until after the seventh year.

Dissection.—The septal cartilage and thin bony part of the septum must now be removed piecemeal. The removal must

be done very carefully, in order to preserve intact the muco-periosteum which clothes the opposite side of the septum. It is in that muco-periosteum that the nerves and blood-vessels must be examined.

Vessels and Nerves of the Septum Nasi.—The following is a list of the nerves:—

Nerves of Smell, .	Olfactory.
Nerves of Common Sensation, . .	1. Naso-palatine. 2. Medial nasal branch of the anterior ethmoidal nerve. 3. Nasal branches from spheno-palatine ganglion and from the nerve of the pterygoid canal (O.T. Vidian).

The Medial Group of Olfactory Nerves.—The medial group of olfactory nerves is associated with the muco-periosteum of the upper part of the nasal septum and the various nerve filaments are barely distinguishable, except in a fresh part; further, they are so soft that it is hardly possible to isolate them. They proceed upwards in grooves on the surface of the perpendicular lamina of the ethmoid, and leave the nasal cavity through the medial series of apertures in the cribriform plate of the same bone.

Nervus Naso-palatinus.—The naso-palatine nerve is a long slender twig which can easily be detected upon the deep surface of the muco-periosteum of the septum. It springs from spheno-palatine ganglion, and enters the nasal cavity through the spheno-palatine foramen. In the first part of its course it runs medially, upon the inferior surface of the body of the sphenoid. Having gained the nasal septum, it changes its direction and passes downwards and forwards, in a shallow groove on the surface of the vomer, under cover of the muco-periosteum. Finally, it enters the foramen of Scarpa, and, where the two foramina of Scarpa open into the common incisive foramen, the nerves of opposite sides unite in a plexus from which branches are given to the mucous membrane covering the anterior part of the hard palate. The naso-palatine nerve is accompanied by the posterior nasal septal artery; and, as it lies on the surface of the vomer, it supplies some small twigs to the muco-periosteum of the septum nasi.

A few *nasal branches* from the *spheno-palatine ganglion*, and also from the *nerve of the pterygoid canal*, reach the muco-periosteum over the superior and posterior part of the septum. They are very minute, and it is questionable if the dissector

will be able to discover any trace of them in an ordinary part.

The *medial nasal branches of the anterior ethmoidal nerve* will be found descending over the anterior part of the nasal septum. They may be traced as far as the vestibule.

The *arteries* which convey blood to the septum nasi are: (1) the posterior nasal septal branch of the spheno-palatine artery, which accompanies the naso-palatine nerve; (2) a branch of the anterior ethmoidal, accompanying the medial branches of the anterior ethmoidal nerve; (3) some minute twigs, to the upper part of the septum, from the posterior ethmoidal artery; (4) the septal branch of the superior labial artery, which is distributed to the lower and front part of the septum.

Dissection.—Disengage the naso-palatine nerve and the medial branches of the anterior ethmoidal nerve from the surface of the muco-periosteum of the septum, in order that, afterwards, they may be traced to their origins. Then, with scissors, divide the muco-periosteum along the roof ot the nasal cavity and turn it down. When that is done, the opposite nasal cavity will be exposed.

Cava Nasi.—The nasal cavities are two chambers placed one on each side of the septum nasi. They are narrow, but the vertical depth and antero-posterior length of each cavity is very considerable. The width increases somewhat from above downwards; thus, in the upper part, the superior concha is separated from the septum by an interval of only 2 mm., whilst lower down a space of 4 or 5 mm. intervenes between the inferior concha and the septum. Each nasal cavity presents a medial wall formed by the septum, a lateral wall, a roof, a floor, and an anterior and a posterior aperture.

The *anterior apertures* of the nasal cavities, or *nostrils*, are two oval orifices which open upon the face and look downwards. The *posterior apertures*, or *choanæ*, open into the naso-pharynx and look backwards and downwards.

The narrow *roof* of the nasal cavity consists of a *middle*, horizontal portion, formed by the cribriform plate of the ethmoid bone, and of an anterior and a posterior sloping part. The *anterior part* is formed by the narrow grooved nasal surface of the frontal spine of the frontal bone, by the nasal bone, and by the angle between the lateral cartilage and the septal cartilage. The *posterior part* of the roof is composed of the anterior and inferior surfaces of the body of the

sphenoid, and also of the ala of the vomer, the sphenoidal process of the palate bone, and the vaginal process of the medial pterygoid lamina, all of which are applied to the inferior surface of the body of the sphenoid.

The *floor* of the nasal cavity is of considerable width. It is formed by the palatal processes of the maxilla and the palate bones, and is concave from side to side. Further, it presents

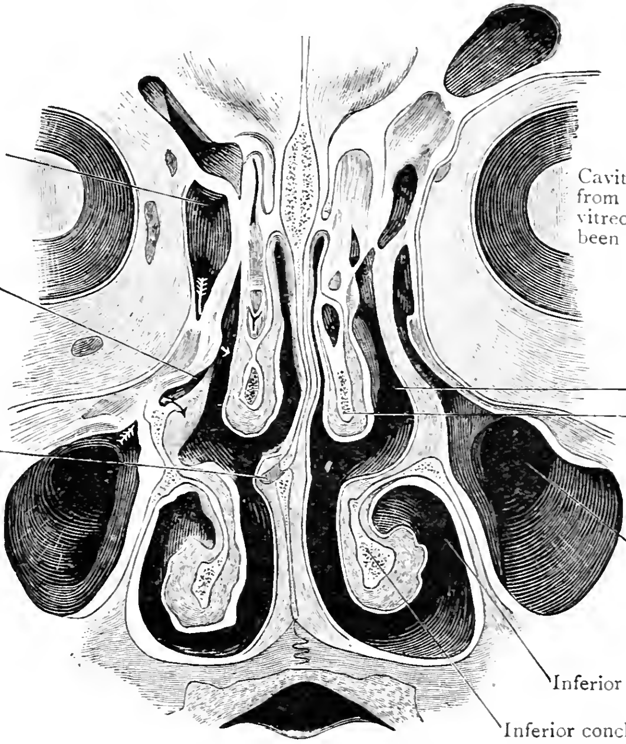

FIG. 115.—Posterior aspect of Frontal section through the Nasal Cavities opposite the Crista Galli of the Ethmoid Bone.

The *upper arrow* shows the opening of an anterior ethmoidal cell into the hiatus semilunaris. The *lower arrow* passes from the maxillary sinus into the hiatus semilunaris.

a gentle antero-posterior slope, being slightly higher anteriorly than posteriorly. On the anterior part of the floor, and close to the septum nasi, the dissector may see a minute funnel-shaped depression of the muco-periosteum leading into the incisive foramen. The depression is of interest from a developmental point of view; for it is a vestige of the extensive communication which existed in the embryo between the cavities of the nose and the mouth.

Lateral Wall of the Nasal Cavity.—The lateral wall of each nasal cavity is rendered uneven by the projection of the three conchæ (O.T. turbinal bones).

The part which the different bones take in the formation of the lateral wall of the cavity of the nose must in the first place be studied in a sagittal section through the macerated skull, and the dissector should constantly refer to such a preparation during the dissection. Anteriorly, it is formed by the lateral cartilage, the alar cartilage, the nasal bone, and the frontal process of the maxilla. More posteriorly the lacrimal, the ethmoid, and the inferior concha, and a portion of the body of the maxilla, enter into its construction; whilst still more posteriorly are the perpendicular part of the palate bone and the medial pterygoid lamina of the sphenoid. Placed in relation to the lateral aspect of the lateral wall are the ethmoidal air-cells, which intervene between the upper part of the nasal cavity and the orbit, whilst, at a lower level, the great air sinus of the maxilla, the *maxillary sinus*, is situated immediately to the lateral side of the nasal cavity (Fig. 115).

Turning now to the dissection, the dissector will see that the lateral wall is separable into three areas or districts. They are—(1) the vestibule; (2) the atrium meatus medii; (3) the region of the conchæ and the intervening meatuses.

Vestibulum Nasi.—The *vestibular part* (Fig. 116, 6, 6′) of the lateral wall is a depression of a somewhat oval form placed immediately above the aperture of the nostril. It is partially divided into an upper and lower portion by a short ridge, which projects forwards from its posterior boundary; and in the whole of its extent it is clothed by ordinary integument. From the skin a number of stout, stiff hairs, termed *vibrissæ*, project (Fig. 116, 5). The vibrissæ which spring from the anterior part of the region incline backwards, whilst those which are implanted into the posterior part are directed forwards; in that manner a sieve-like arrangement is provided at the anterior aperture of the nose. The vestibular part of the lateral wall is placed opposite the corresponding area on the septum nasi, and the two together constitute an ampullated entrance to the nasal cavity. The capacity and shape of the vestibule are influenced to a certain extent by the contraction of the nasal muscles.

Atrium Meatus Medii.—The atrium of the middle meatus of the nasal cavity (Fig. 116, 8) is placed above, and slightly posterior to, the vestibular district, and it receives its name from the fact that it lies immediately anterior to the middle meatus. It is slightly hollowed out and concave, and at its upper part, near the nasal bone, a feeble elevation termed the *agger nasi*

may be noticed; the agger nasi begins close to the anterior part of the attached margin of the middle concha, and runs obliquely downwards and forwards. It represents an additional concha which is present in some mammals. A slight depression above the agger nasi, which leads posteriorly to

the olfactory district of the lateral wall of the nasal cavity, is the *sulcus olfactorius*.

Conchæ (O.T. **turbinal bones**).—Posterior to the vestibule and the atrium are the conchæ, with the intervening meatuses. The *superior concha* (Fig. 116, 12), which projects from the labyrinth of the ethmoid bone, is very short, and is placed

on the upper and posterior part of the lateral wall of the cavity. Its free border begins a little below the centre of the cribriform plate, and passes obliquely downwards and backwards, to a point immediately below the body of the sphenoid, where it ends. The *middle concha* (Fig. 116, 14) also is a part of the ethmoid. Its free border begins a short distance below the anterior end of the cribriform plate, and at first takes a vertical course downwards; then, bending suddenly, it passes backwards, and it ends midway between the body of the sphenoid and the posterior border of the hard palate. The *inferior concha* (Fig. 116, 15) is an independent bone; it extends backwards, upon the lateral wall of the nasal cavity, midway between the middle concha and the floor of the nose. Its lower free margin is somewhat convex downwards.

Meatus Nasi.—The *superior meatus* (Fig. 116, 13) is a short narrow fissure between the superior and middle conchæ. The posterior ethmoidal cells open into its upper and anterior part, by one, or, in some cases, by several apertures.

To bring the apertures into view, turn the superior concha aside, introduce the blade of a pair of forceps under its entire length, and force it upwards. Care should be taken not to injure the mucous membrane more than is necessary.

The *middle meatus* is a much more roomy passage than the superior meatus; it extends backwards from the atrium, between the middle and inferior conchæ. To expose it tilt the middle concha forcibly upwards and backwards.

The upper and anterior part of the middle meatus leads into a funnel-shaped passage which runs upwards into the corresponding frontal sinus. The passage is called the *infundibulum*, and it constitutes the channel of communication between the frontal sinus and the nasal cavity.

Upon the lateral wall of the middle meatus a deep curved groove or gutter, which commences at the infundibulum and runs from above downwards and backwards, will be seen. The groove is termed the *hiatus semilunaris* (Fig. 117), and in it are the openings of the anterior ethmoidal cells and the maxillary sinus. The slit-like opening of the maxillary sinus lies in the posterior part of the hiatus semilunaris. The upper boundary of the hiatus semilunaris is prominent and bulging. It is termed the *bulla ethmoidalis*. On or

above the bulla is the aperture of the middle ethmoidal cells (Fig. 117).

Dissection.—Open the maxillary sinus from the lateral side, by sawing upwards through the zygomatic process of the maxilla. Then examine the interior of the sinus.

The orifice by means of which the great maxillary air sinus communicates with the middle meatus lies in the medial wall of the sinus, much nearer the roof than the floor—a position highly unfavourable for the escape of fluids which may collect in the cavity. Sometimes, however, a second orifice,

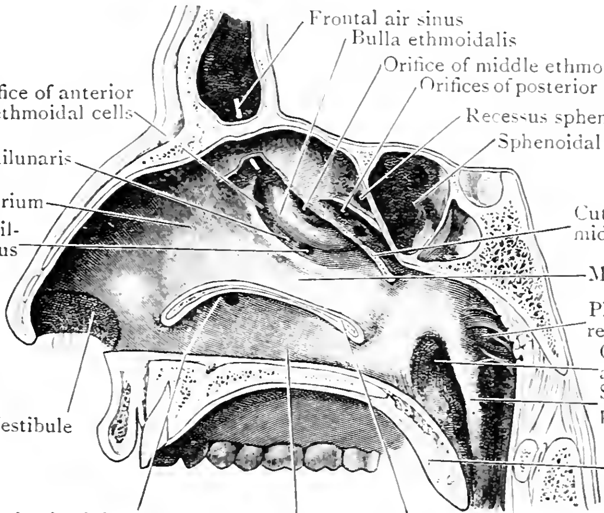

FIG. 117.—Lateral wall of Nasal Cavity and Naso-pharynx. The three conchæ have been removed.

circular in outline, will be found. If it is present it is situated lower down, and it opens into the middle meatus, immediately above the middle point of the attached margin of the inferior concha.

The dissector should note that, on account of the relationship of the infundibulum to the hiatus semilunaris and of the latter to the opening of the maxillary sinus, there is a tendency, in some cases, for the secretion of the frontal sinuses to flow into the maxillary sinus.

The *inferior meatus* is the horizontal passage which lies between the inferior concha and the floor and lateral wall

of the nasal cavity. It is placed posterior to the vestibule, and the free border of the inferior concha turns downwards and limits it anteriorly (Fig. 117). On that account, and because its floor slopes downwards and backwards, the inferior meatus is more accessible to the current of expired air than to the current of inspired air. In the anterior part of the inferior meatus will be found the opening of the naso-lacrimal duct, which conveys the tears to the nasal cavity (Fig. 117).

Dissection.—**To bring the aperture of the naso-lacrimal canal into view, remove a small portion of the anterior part of the inferior concha with the scissors (Fig. 117).**

The orifice of the naso-lacrimal duct varies in form, according to the manner in which the mucous membrane is arranged around it. Sometimes it is wide, patent, and circular; at other times the mucous membrane is prolonged over the opening, reducing its size and acting as a flap valve to the orifice. In some cases, indeed, the orifice may be so minute that it is difficult to find. Its continuity with the lacrimal sac should in all cases be established by passing a probe, from above downwards, through the naso-lacrimal canal (Fig. 9).

The space above and behind the superior concha is termed the *recessus spheno-ethmoidalis*, and in its posterior part is the aperture of the sphenoidal air sinus (Fig. 117). The orifice of the sphenoidal air sinus may be circular or slit-like, according to the manner in which the mucous membrane is disposed around it.

The term *meatus communis* is applied to the narrow cleft-like portion of the nasal cavity which extends from the roof to the floor between the septum medially and the conchæ laterally; and the part of the cavity which lies posterior to the conchal region, and between it and the choanæ, is the *naso-pharyngeal meatus* (Fig. 116, 17).

Muco-periosteum of the Lateral Walls of the Nasal Cavities.—It has been noted that the vestibule is lined with integument. The remainder of each lateral wall of the nasal cavity is covered with mucous membrane which is so closely blended with the subjacent periosteum that the two are inseparable and form a *muco-periosteum*. A similar membrane covers the roof and the floor. The muco-periosteum is continuous, through the naso-lacrimal duct, with the ocular

conjunctiva; through the various apertures, with the delicate lining membrane of the air-cells which open into the nasal cavity, and, through the choanæ, with the pharyngeal mucous membrane. On the lateral wall, as on the septum, the muco-periosteum is separable into an upper, olfactory, and a lower, respiratory portion; but the subdivision cannot be appreciated by the naked eye, for the one district passes into the other without any sharp line of demarcation. The *olfactory region* comprises merely the region of the upper concha; the *respiratory region* includes the middle and inferior conchæ, the middle meatus, the inferior meatus, and the atrium. On the lower part of the lateral wall the muco-periosteum is thick and spongy, more particularly over the lower borders and posterior extremities of the middle and inferior conchæ, where the membrane presents an irregular surface and forms soft, bulging cushions. The spongy condition is due to the presence of a rich venous plexus, the vessels of which run, for the most part, in an antero-posterior direction. In the region of the inferior concha, the veins are so numerous that the muco-periosteum assumes the character of cavernous tissue, and is sometimes spoken of as the "erectile body." When turgid with blood it swells out and obliterates the interval between the concha and the septum. The muco-periosteum of the floor, meatuses and atrium, is smoother than, and not so thick as, that over the conchæ. Everywhere, numerous mucous glands are embedded in it, and the minute punctiform orifices of the ducts are visible to the naked eye. In the olfactory region the lining membrane of the nose, in the fresh state, is of a yellowish colour, and it is softer and more delicate than in the respiratory part.

The great vascularity of the mucous membrane of the nose is, doubtless, for the purpose of moistening and raising the temperature of the inspired air.

Nerves and Vessels on the Lateral Wall of the Nasal Cavity:—

Nerves of Smell, .	Olfactory nerves.
Nerves of Common Sensation, . .	1. Lateral nasal branches of anterior ethmoidal. 2. Nasal branch of anterior superior alveolar. 3. Posterior superior nasal branches from spheno-palatine ganglion and from the nerve of the pterygoid canal. 4. Two posterior inferior nasal branches from the anterior palatine nerve.

The *olfactory nerves* are from twelve to twenty in number. They are formed by numerous fine nerve filaments, which spring from the olfactory cells of the olfactory mucous membrane, and they are arranged in two groups; a *medial* or *septal group*, from the upper part of the septum (p. 307), and a *lateral group*, from the upper third of the lateral wall of the nasal cavity. The nerve filaments lie in the muco-periosteum, but the nerves which they form are lodged in shallow bony grooves and small bony canals in the walls of the nasal cavity. At the roof of the nose the nerves pass through the foramina in the cribriform plate of the ethmoid; then they pierce the meninges, from which they derive sheaths, and they end in the lower part of the olfactory bulb of the same side.

Dissection.—Follow the naso-palatine nerve, which was exposed on the nasal septum, across the roof of the nasal cavity to the spheno-palatine foramen in the lateral wall of the nose. By dissecting carefully in the muco-periosteum in the neighbourhood of the foramen, in a good part, the dissector may be able to display one or more of the posterior superior nasal nerves. At the same time he should display the spheno-palatine branch of the internal maxillary artery which enters the nose through the spheno-palatine foramen.

The *posterior superior nasal nerves* arise from the spheno-palatine ganglion and from the nerve of the pterygoid canal. In spite of the fact that they are minute filaments, the dissector should endeavour to trace them to their distribution upon the lateral wall. They enter the nose through the spheno-palatine foramen, which is situated at the posterior end of the superior meatus; and are distributed to the muco-periosteum over the upper and middle conchæ, and the posterior part of the septum.

Dissection.—Make a vertical incision through the muco-periosteum over the posterior part of the medial pterygoid lamina, then carefully raise the membrane, reflect it forwards and seek for the inferior nasal nerves. They both pierce the perpendicular plate of the palate bone; the upper one at a point on a level with the interval between the posterior ends of the middle and inferior conchæ, and the lower at the level of the posterior end of the inferior concha.

The *inferior nasal nerves* are two in number; they both arise from the anterior palatine nerve.

The *upper* of the two inferior nasal nerves emerges through a small aperture in the perpendicular part of the palate bone, at a point between the posterior extremities of the middle and

inferior conchæ. It divides into an ascending and descending branch. Both run forwards; the former on the middle concha, the latter on the inferior concha. The *lower* of the two inferior nasal nerves appears through a foramen in the perpendicular part of the palate bone, immediately posterior to the inferior concha, upon which it is distributed.

The *anterior ethmoidal nerve* (O.T. *nasal*) should be exposed as it descends in the groove upon the deep surface of the nasal bone (p. 252). It gives medial branches to the septum, and lateral branches to the muco-periosteum over the anterior part of the lateral wall, and to the anterior parts of the middle and inferior conchæ.

The main *artery* of supply to the nasal muco-periosteum is the *spheno-palatine*, a branch of the internal maxillary. It gains entrance to the nasal cavity through the spheno-palatine foramen, in company with the posterior superior nasal nerves. Its septal branch accompanies the naso-palatine nerve, whilst others are distributed upon the lateral wall of the cavity. Several twigs are given also by the *descending palatine branch* of the internal maxillary and the *two ethmoidal arteries*, but these are small and will be seen only in cases where the injection of the subject has been unusually successful.

SPHENO-PALATINE GANGLION AND INTERNAL MAXILLARY ARTERY.

The spheno-palatine ganglion is situated in the pterygo-palatine fossa, on the lateral side of the spheno-palatine foramen; and at this stage it can be exposed best by a dissection from the medial or nasal side.

Dissection.—The muco-periosteum has already been removed from the posterior part of the lateral wall of the nasal cavity, and the inferior nasal branches of the anterior palatine nerve have been found piercing the perpendicular part of the palate bone. The dissector cannot fail to notice the course taken by the trunk from which those filaments arise. The lamina of bone which forms the medial wall of the pterygo-palatine canal is so thin that the nerve can be distinctly seen through it. By carefully opening up the canal with a small chisel, and following the anterior palatine nerve upwards, the dissector will be led to the ganglion in the pterygo-palatine fossa. The naso-palatine nerve should at the same time be traced to its origin. The ganglion is so hemmed in by the bony walls of the fossa that it is very difficult to display it thoroughly;

but by removing the orbital process of the palate bone, and a portion of the body of the sphenoid, with the bone forceps, the dissector may expose it more or less satisfactorily. In the same restricted space will be found the terminal portion of the internal maxillary artery, from which numerous branches are given off.

Ganglion Sphenopalatinum.—The spheno-palatine ganglion is a small, triangular flattened body, which is lodged in the pterygo-palatine fossa. It is embedded in fat, and is surrounded by the terminal branches of the internal maxillary artery. Two stout spheno-palatine branches descend to it from the maxillary nerve, but only some of their fibres end in the ganglion; the remainder are continued directly into the nasal and palatine nerves which proceed from the ganglion. The spheno-palatine branches may be regarded as constituting the *sensory roots* of the ganglion.

From the spheno-palatine ganglion branches are given off which radiate in four directions—viz., medially, to the nose; downwards, to the palate; backwards, to establish connections with the facial nerve and carotid plexus, as well as to supply the mucous membrane of the pharynx; and, forwards, to the orbit.

Medial branches, .	Posterior superior nasal nerves.
Descending branches,	Anterior palatine. Middle palatine. Posterior palatine.
Posterior branches, .	Nerve of pterygoid canal. Some lateral posterior superior nasal branches.
Anterior branches, .	Orbital.

From the internal maxillary artery twigs are given off which accompany the above-mentioned nerves.

Posterior Superior Nasal Nerves.—There are two groups of the posterior superior nasal nerves, a medial and a lateral. The medial branches pass through the spheno-palatine foramen and across the roof of the nasal cavity to the posterior part of the septum. The largest of them, the naso-palatine nerve, runs downwards and forwards in a groove on the surface of the vomer (p. 307). Some of the branches of the lateral posterior group also pass through the spheno-palatine foramen and are distributed to the superior meatus, to the superior and middle conchæ, and to the posterior ethmoidal air cells. Other branches of the lateral group pass backwards, some in the muco-periosteum of the upper and posterior part

of the nasal cavity, and one in the pharyngeal canal (O.T. pterygo-palatine or pharyngeal nerve). They are distributed to the muco-periosteum of the posterior part of the roof of the nasal cavity, to the adjacent parts of the wall of the pharynx, to the sphenoidal air sinus, and to the pharyngeal part of the auditory tube.

The *descending branches* are the palatine nerves, and with them are incorporated the posterior inferior nasal nerves. The palatine nerves are three in number, anterior (O.T. great or posterior palatine), middle, and posterior. As a rule the three spring, by a common trunk, from the lower aspect of the ganglion. The trunk descends in the pterygo-palatine canal, which has been opened up already, but to expose the nerves a dense fibrous investment must also be removed. The nerve-trunk will then be seen breaking up into its constituent parts.

Dissection.—Trace, in the first instance, the two smaller nerves—viz., the middle and posterior palatine branches. They leave the main canal and enter the lesser palatine canals, which conduct them through the pyramidal process of the palate bone. It is well to secure the nerves as they emerge from the lower openings of the canals, before opening the canals. The dissector can readily find them by dissecting posterior to the hamulus of the medial pterygoid lamina and gently separating the soft parts from the under aspect of the pyramid of the palate bone. As the dissection is being made from the medial side, the *middle palatine nerve* will be first encountered, and it will be seen to pass backwards into the soft palate, under cover of the tendinous expansion of the tensor veli palatini.[1] The tensor must be divided, in order that the nerve may be followed to its distribution. The *posterior palatine nerve* will be found issuing from its canal a short distance to the lateral side of the preceding nerve. It is distributed to the soft palate in the neighbourhood of the palatine tonsil. It is smaller than the middle palatine nerve, and is sometimes absent. The large *anterior palatine nerve* should now be followed onwards to the hard palate. To do that, open up the lower part of the pterygo-palatine canal by removing a small portion of the posterior and lateral part of the horizontal plate of the palate bone.

The *anterior palatine nerve* is the largest branch of the spheno-palatine ganglion. It descends through the pterygo-palatine canal, accompanied by the great palatine branch of the internal maxillary artery; it enters the palate through the greater palatine foramen and runs forwards, in a groove on the

[1] The present is a good opportunity to observe the corrugated or wrinkled appearance of the tendon of the tensor, as it passes under the hamulus.

lower aspect of the hard palate, towards the incisive foramen. It supplies the gum, the mucous membrane, and the glands of the vault of the mouth; and, in the neighbourhood of the incisive foramen, it communicates with the naso-palatine nerve. As it passes down the pterygo-palatine canal the posterior inferior nasal branches, which were enclosed in its sheath, leave it and enter the nasal cavity (p. 316).

Whilst tracing the anterior palatine nerve in the palate, the dissector should note the numerous glands which are placed under the mucous membrane of the vault of the mouth, and the manner in which they indent the bone.[1]

Dissection.—The dissector will experience some difficulty in exposing the nerves in the pharyngeal and pterygoid canals, which are very inaccessible.

To open up the pharyngeal canal the sphenoidal process of the palate bone must be cautiously removed with the bone forceps, and then the dissector should proceed to open up the pterygoid canal (O.T. Vidian), which traverses the root of the pterygoid process. As the bone is very hard and brittle in this region, the dissection must be effected very carefully.

The *nerve of the pharyngeal canal* belongs to the posterior superior nasal group (p. 318).

Nervus Canalis Pterygoidei (O.T. *Vidian*).—The nerve of the pterygoid canal is formed by a junction between the *greater superficial petrosal branch* of the facial and the *great deep petrosal branch* of the carotid plexus. It traverses the pterygoid canal, and joins the posterior aspect of the spheno-palatine ganglion, of which it may be considered to represent both the *motor* and *sympathetic root*. In the canal it is invested by a strong fibrous envelope, and when that is removed the nerve may sometimes be noticed to break up into a fine plexus which surrounds the accompanying artery. It has already been seen to give some fine filaments to the muco-periosteum of the nose.

Rami Orbitales.—The orbital branches of the ganglion are exceedingly minute; they pass forwards, through the inferior orbital fissure, to supply the periosteum of the orbit.

Termination of Internal Maxillary Artery.—The internal

[1] An equally good method of tracing the anterior palatine nerve is to remove the palatal processes of the palate and maxilla with the bone forceps, and then to display the nerve and artery on the upper surface of the mucous membrane and glands.

maxillary artery breaks up into its terminal branches in the pterygo-palatine fossa. They are—

1. Posterior superior alveolar (p. 174).
2. The infra-orbital (p. 303).
3. The descending palatine.
4. The spheno-palatine.

Arteria Palatina Descendens.—The descending palatine artery is a terminal branch of the internal maxillary artery. As it descends, in the pterygo-palatine fossa, it gives off, usually, the artery of the pterygoid canal, and, as it enters the pterygo-palatine canal, several small palatine arteries spring from it; then it becomes the *great palatine artery.* The great palatine artery descends through the great palatine foramen into the hard palate; there it runs forwards to reach the incisive foramen, through which it passes into the nasal cavity to anastomose with the posterior artery of the septum, which is an offset of the spheno-palatine artery.

The *small palatine arteries* spring from the descending palatine, immediately before it becomes the great palatine artery, in the upper part of the pterygo-palatine canal; they descend through the small palatine canals, and are distributed to the soft palate, the palatine arches, and to the palatine tonsil.

Arteria Spheno-palatina.—The spheno-palatine artery enters the nasal cavity through the spheno-palatine foramen. It gives off (1) a branch to the sphenoidal air sinus, (2) a branch which passes backwards through the pharyngeal canal (O.T. pterygo-palatine artery) to be distributed to the roof of the posterior part of the nasal cavity and to the roof of the pharynx; that branch anastomoses with the ascending pharyngeal artery. Then the spheno-palatine artery divides into lateral and septal posterior nasal branches. The lateral branches are distributed to the lateral wall of the nasal cavity, where they anastomose with the branches of the posterior and anterior ethmoidal arteries, and with the lateral nasal branch of the external maxillary. They supply not only the muco-periosteum of the lateral wall of the nasal cavity, but also the muco-periosteum of the air sinuses which open into the cavity. The posterior septal branch of the spheno-palatine artery accompanies the posterior nasal septal nerve along the surface of the vomer; it anastomoses with the great palatine artery, and with the septal branch of the superior labial artery.

THE LARYNX.

The portions of the mandible which are still attached, by mucous membrane, to the sides of the tongue, should be removed, and the dissection of the larynx should be commenced.

General Construction and Position.—The larynx is the upper expanded portion of the wind-pipe which is specially modified for the production of the voice. Its walls are composed of cartilages, muscles, ligaments and membranes, and it has an internal lining of mucous membrane. Before proceeding with the dissection the student should study the form and connections of the nine laryngeal cartilages in a permanent specimen (*v.* p. 338).

The larynx is placed in the upper and anterior part of the neck, where it forms a marked projection. It lies below the hyoid bone and tongue, and is directly continuous with the trachea inferiorly. *Anteriorly* it is covered by the skin and fasciæ, and, on each side of the median plane, by two thin strata of muscles—viz., the sterno-hyoid and omo-hyoid; the sterno-thyreoid and the thyreo-hyoid. Frequently a narrow process of the thyreoid gland, termed the *pyramidal lobe*, is continued upwards on its anterior surface. On *each side* a lobe of the thyreoid gland is prolonged upwards upon it, deep to the muscles; and it is related to the great vessels of the neck. *Posteriorly* it is in relation to the pharynx, which separates it from the prevertebral muscles. If the tip of the epiglottis is taken as its upper limit, the larynx, in the adult, may be regarded as being placed anterior to that portion of the vertebral column which extends from the lower border of the second to the lower border of the sixth cervical vertebra; but the position is not fixed: it varies with the movements of the head, and also during deglutition and phonation.

Interior of the Larynx.—The cavity of the larynx is smaller than might be expected from an inspection of its exterior. When its interior is examined from above, it will be seen to be subdivided into three portions by two elevated folds of mucous membrane which extend antero-posteriorly, and project inwards from each side of the cavity. The upper pair of folds are termed the *plicæ ventriculares* (O.T. *false vocal cords*); the lower pair receive the name of the *plicæ vocales*

(O.T. *true vocal cords*). The vocal folds are the chief agents in the production of the voice, and the larynx is so constructed that changes in their relative position, and in their degree of tension, are brought about by the action of the muscles and the recoil of the elastic ligaments.

Vestibulum Laryngis.—The vestibule is the upper subdivision of the laryngeal cavity (Figs. 111, 119); it extends from the superior aperture (*aditus laryngis*) of the larynx down to the ventricular folds. Its lower part is compressed from side to side. Its width, therefore, diminishes from above downwards, whilst, owing to the obliquity of the aditus, the anterior wall is longer than the posterior. The *anterior wall* is formed by the posterior surface of the epiglottis and the thyreo-epiglottic ligament, both covered with mucous membrane. It descends obliquely from above downwards and slightly forward and becomes narrower as it approaches the anterior ends of the ventricular folds. Each *side wall* of the vestibule is formed by the medial surface of a fold of mucous membrane called the ary-epiglottic fold. For the most part it is smooth and slightly concave, but in its posterior part the mucous membrane bulges medially, in the form of two vertical elevations, placed one posterior to the other. The anterior elevation is formed by the enclosed cuneiform cartilage and a mass of glands associated with it;

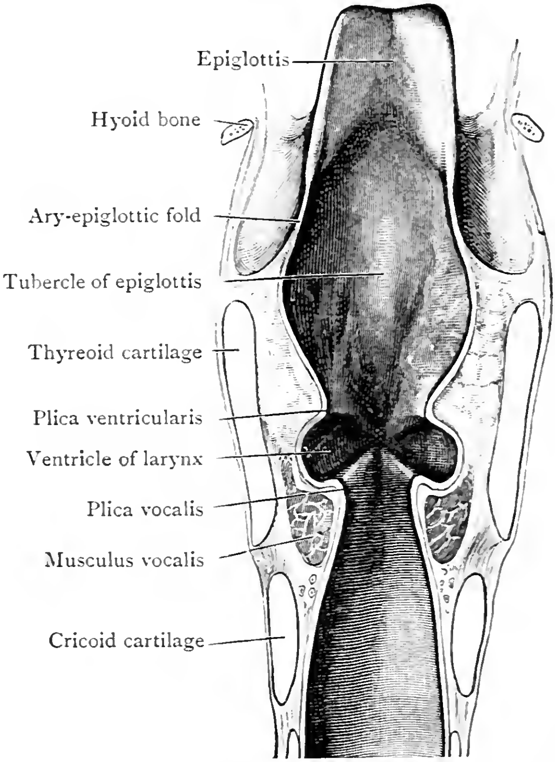

FIG. 118.—Frontal section through the Larynx, to show the Compartments.

the posterior elevation is due to the anterior margin of the arytænoid cartilage and the corniculate cartilage. A shallow groove descends between the two elevations; it terminates below by running into the interval between the ventricular and the vocal folds. The *posterior wall* of the vestibule is narrow. It is formed by the mucous membrane which covers the anterior surface of the arytænoideus muscle and it occupies the interval between the two arytænoid cartilages.

The *aditus laryngis* has already been examined, in the dissection of the pharynx (p. 291). The parts which bound it should again be carefully studied.

The *epiglottis* projects upwards, posterior to the median thyreo-hyoid ligament, the hyoid bone and the base of the tongue. Its lingual or anterior surface is free in the upper part of its extent only, and is attached to the pharyngeal part of the tongue by a prominent median fold of mucous membrane, termed the *glosso-epiglottic fold*. Two lateral folds are also present; they connect its margins with the walls of the pharynx at the side of the tongue, and are called the *pharyngo-epiglottic folds*. Between the two layers of mucous membrane which constitute each of the three folds, there is a small amount of elastic tissue. The depression on each side, between the tongue and the epiglottis, which is bounded by the glosso-epiglottic and a pharyngo-epiglottic fold is termed a *vallecula* (Fig. 119). The posterior free surface of the epiglottis forms the greater part of the anterior boundary of the vestibule of the larynx. The upper part of this surface is convex, owing to the manner in which the upper margin is curved towards the tongue; below the convexity there is a slight concavity, and still lower there is a marked bulging, over the upper part of the thyreo-epiglottic ligament. The last projection is called the *tubercle of the epiglottis*; it is a conspicuous object in laryngoscopic examinations of the larynx.

Each *ary-epiglottic fold* of mucous membrane encloses between its two layers some connective tissue, the ary-epiglottic muscle, and, posteriorly, the cuneiform cartilage, and the corniculate cartilage, which surmounts the arytænoid cartilage. As already mentioned, the two small nodules of cartilage produce elevations on the medial layer of the posterior part of the ary-epiglottic fold, which are easily seen when the larynx is examined with the laryngoscope.

The **Middle Subdivision of the Laryngeal Cavity** (Fig. 118)

is the smallest of the three sections. It is bounded by the ventricular folds, above, and by the vocal folds below; it communicates with the vestibule above, and with the inferior compartment of the larynx below.

Plicæ Ventriculares (O.T. *False Vocal Cords*).—The ventricular folds are two prominent mucous folds which extend, antero-posteriorly, across the side walls of the laryngeal cavity. They are soft and somewhat flaccid, and their free borders are slightly arched, with the concavities looking downwards. Each fold contains—(1) a ventricular ligament; (2) numerous glands, which are aggregated chiefly in its middle part; and (3) a few muscle fibres. The interval between the ventricular folds is termed the *rima vestibuli*; it is consider-

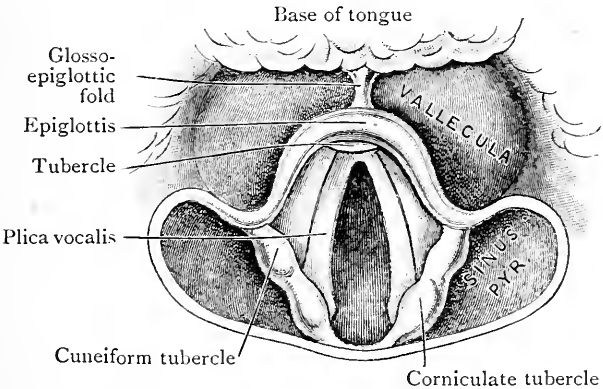

FIG. 119.—The Larynx as seen in the living person by means of the Laryngoscope.

ably wider than that between the vocal folds. It follows, therefore, that the four folds are distinctively visible when the cavity of the larynx is examined from above, but the vocal folds alone can be seen when the cavity is examined from below.

Plicæ Vocales (O.T. *True Vocal Cords*).—The vocal folds are placed below the ventricular folds, and extend from the angle between the laminæ of the thyreoid cartilage, anteriorly, to the vocal processes of the arytænoid cartilages, posteriorly. Each vocal fold is sharp and prominent, and its mucous membrane is thin and is firmly bound down to the subjacent vocal ligament. In colour it is pale, almost pearly white, whilst, posteriorly, the point of the vocal process of the arytænoid cartilage, which stands out in relief, presents a yellowish tinge. In frontal section each vocal fold is somewhat prismatic in form, and the free border looks upwards and medially (Fig. 118).

The vocal folds are the agents by means of which the voice is produced. The ventricular folds are of little importance in that respect; indeed, they can be destroyed, in great part, without any appreciable effect upon the voice.

The *rima glottidis* is the elongated fissure by means of which the middle compartment of the larynx communicates with the lower subdivision. It is placed somewhat below the middle of the laryngeal cavity, of which it constitutes the narrowest part. Anteriorly, it is the interval between the vocal folds; posteriorly, it is the interval between the bases and vocal processes of the arytænoid cartilages (Fig. 121). It is composed, therefore, of two very distinct parts—(1) a narrow, anterior portion, between the vocal folds, involving less than two-thirds of its length, and called the *pars intermembranacea*; (2) a broader, shorter portion, between the arytænoid cartilages, termed the *pars intercartilaginea*. The form of the rima glottidis undergoes frequent alterations in the living person. During ordinary quiet respiration it is lanceolate in outline, and the intermembranous part has the form of an elongated triangle, with the base directed backwards. When the rima glottidis is widely opened the broadest part of the cleft lies between the extremities of the vocal processes of the arytænoid cartilages, and there each side of the rima presents a marked angle. The two vocal

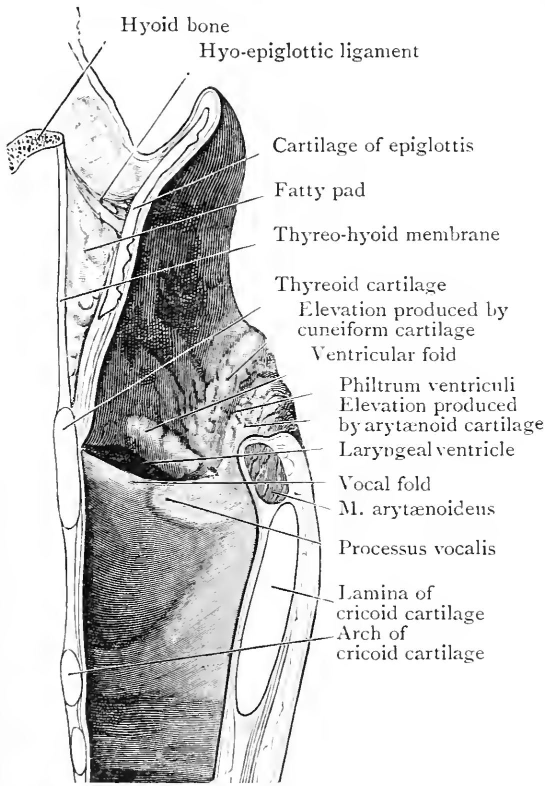

FIG. 120.—Median section through the Larynx, to show the Side Wall of its Right Half.

folds may, on the other hand, be approximated so closely to each other, as when a high note is sung, that the intermembranous part is reduced to a linear chink. The length of the entire fissure differs considerably in the two sexes. In the male its average length is 23 mm.; in the female, 17 mm.

In the side wall of the larynx, in the interval between the ventricular and the vocal folds, there is a pocket-like depression or recess, termed the *ventriculus laryngis* (O.T. *laryngeal sinus*).

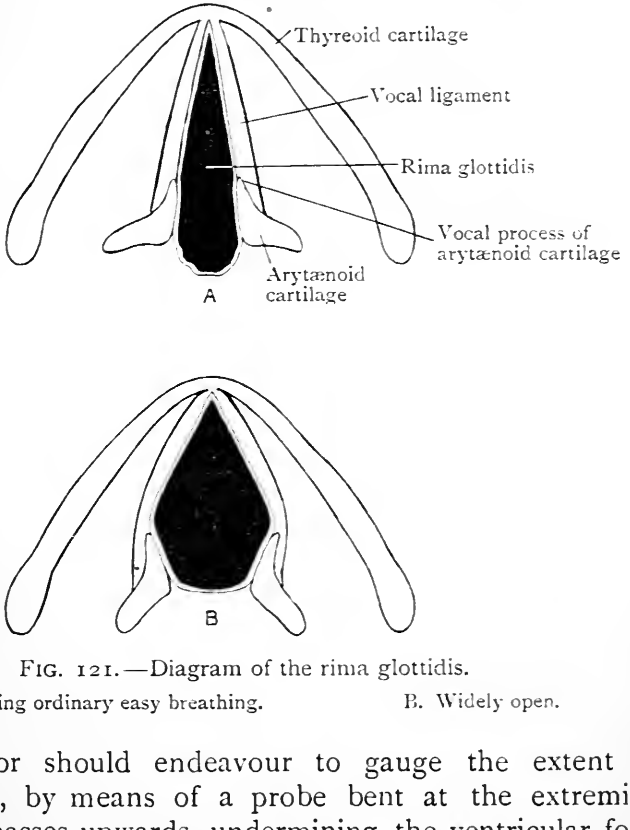

FIG. 121.—Diagram of the rima glottidis.

A. During ordinary easy breathing. B. Widely open.

The dissector should endeavour to gauge the extent of the ventricle, by means of a probe bent at the extremity. The recess passes upwards, undermining the ventricular fold, and its mouth or orifice is narrower than its cavity. Under cover of the anterior part of the ventricular fold a slit-like aperture will be detected. It leads into the *appendix ventriculi* (O.T. *laryngeal saccule*), a small diverticulum, which ascends between the ventricular fold and the lamina of the thyreoid cartilage. The appendix is of variable extent, but, as a rule, it ends blindly at the level of the upper border of the thyreoid cartilage.

Distend the ventricle, and, if possible, the appendix, with cotton wadding. This will greatly facilitate the subsequent dissection.

The **Lowest Subdivision of the Laryngeal Cavity** (Fig. 118) leads directly downwards into the trachea. Above, it is narrow and compressed from side to side, but it gradually widens out until in its lowest part it is circular. It is bounded by the mucous membrane which covers the sloping medial surface of the conus elasticus, and the inner aspect of the cricoid cartilage. It is through the anterior wall of the lowest compartment of the larynx that the opening is made in the operation of laryngotomy.

Mucous Membrane of the Larynx. — The mucous membrane of the larynx is continuous, above, with that lining the pharynx, and below, with the mucous lining of the trachea. Over the laryngeal or posterior surface of the epiglottis it is closely adherent, but elsewhere, above the level of the vocal folds, it is attached loosely by submucous tissue to the adjacent structures. As it passes over the vocal folds it is very thin and tightly bound down, and in inflammatory conditions of the larynx, attended with œdema, that attachment usually prevents the infiltration of the submucous tissue from extending downwards below the rima glottidis.

The mucous membrane of the larynx has a plentiful supply of racemose glands which secrete mucus, but over the surface of the vocal folds they are completely absent.

Dissection.—Place the larynx upon a block so that its anterior surface looks upwards, and fix it in that position with pins. The branches which the external laryngeal nerve gives to the crico-thyreoid muscle should in the first place be followed out; and, carefully preserving the superior and inferior laryngeal vessels and the internal and inferior laryngeal nerves, the dissector should in the next place proceed to remove the thyreoid gland, and the omo-hyoid, sterno-hyoid, sterno-thyreoid, and thyreo-hyoid muscles. The fibres of origin of the inferior constrictor muscle also should be taken away from the thyreoid and cricoid cartilages. The thyreo-hyoid membrane, the crico-thyreoid ligament, and the crico-thyreoid muscles are now exposed, and their attachments may be defined.

Membrana Hyo-thyreoidea.—The thyreo-hyoid membrane is a broad membranous sheet, which occupies the interval between the hyoid bone and the thyreoid cartilage. It is not equally strong throughout, but shows a central thick portion, the *median thyreo-hyoid ligament*, largely composed of elastic

fibres, and cord-like right and left margins, the *lateral thyreo-hyoid* ligaments, whilst in the intervals between the central part and the lateral margins it is thin and weak. The median ligament is attached, above, to the posterior aspect of the upper margin of the body of the hyoid bone; below, it is fixed to the sides of the deep median notch on the upper border of the thyreoid cartilage. The upper part of its anterior surface, therefore, lies behind the hollowed-out posterior surface of the body of the hyoid bone; a mucous bursa is interposed between them, and in certain movements of the head and larynx the upper border of the thyreoid cartilage is allowed to slip upwards behind the hyoid bone. On each side of the strong central part, the thyreo-hyoid membrane is attached, below, to the upper margin of the lamina of the thyreoid cartilage, and, above, to the deep aspect of the greater cornu of the hyoid bone. It is pierced by the internal laryngeal nerve and superior laryngeal vessels. The lateral thyreo-hyoid ligament, which forms the posterior border of the membrane, on each side, is rounded and cord-like, and is composed chiefly of elastic fibres. It extends from the tip of the greater cornu of the hyoid bone to the extremity of superior cornu of the thyreoid cartilage. In it there is usually developed a small, oval cartilaginous or bony nodule, termed the *cartilago triticea* (Fig. 127).

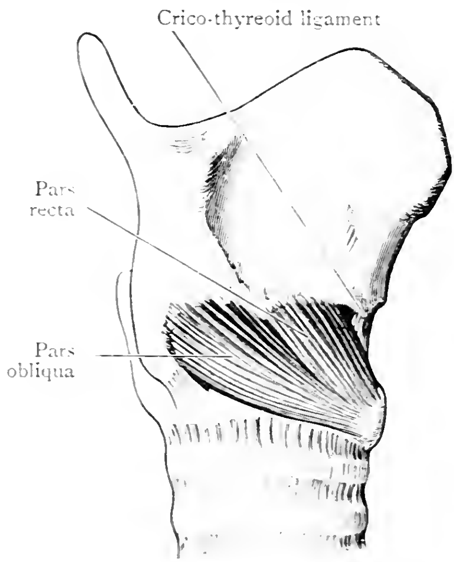

FIG. 122.—The Crico-thyreoid Muscle.

Musculus Crico-thyreoideus.—Each crico-thyreoid muscle is placed on the corresponding side of the cricoid cartilage, and bridges over the lateral portion of the crico-thyreoid interval. It takes origin from the lower border and outer surface of the arch of the cricoid cartilage, whence its fibres spread out in an upward and backward direction, and are inserted into the inner aspect of the lower margin of the

thyreoid lamina, and also into the anterior border of its inferior cornu. As a general rule, it is divided into two parts. The *anterior* or *straight part* is composed of those fibres which are attached to the lamina of the thyreoid cartilage; the *posterior* or *oblique part* is formed of those fibres which are inserted into the inferior cornu of the thyreoid cartilage. It is closely associated with the origin of the inferior constrictor muscle. The crico-thyreoid muscle is supplied by the *external laryngeal branch* of the superior laryngeal nerve. The crico-thyreoid muscles are the chief tensors of the vocal ligaments.

Conus Elasticus.—Extending upwards, from the upper border of the anterior and lateral parts of the cricoid cartilage to the thyreoid and arytænoid cartilages, is a strong elastic membrane, the *conus elasticus*, which is separable into a median and two lateral parts. The median part is the *crico-thyreoid ligament*, which extends from the upper border of the anterior part of the cricoid arch to the lower border of the thyreoid cartilage. Each lateral part (O.T. lateral part of crico-thyreoid membrane) runs upwards and medially and terminates in a free, thickened border, called the *ligamentum vocale*, which lies in the substance of the plica vocalis, and is attached, posteriorly, to the vocal process of arytænoid, and, anteriorly, to the angle of union of the two laminæ of the thyreoid cartilage. The inner surface of the conus elasticus is covered with the mucous membrane of the lowest section of the cavity of the larynx, and the outer surfaces of the lateral parts are in relation with the lateral crico-arytænoid and the thyreo-arytænoideus muscles (Fig. 118).

Dissection.—The position of the larynx must now be reversed. Fix it upon the block in such a manner that its posterior aspect is directed upwards. The œsophagus should then be slit open by a median incision through its posterior wall. Next, remove the mucous membrane which covers the posterior aspect of the cricoid and arytænoid cartilages. Whilst doing that, bear in mind that the inferior laryngeal artery and the inferior laryngeal nerve pass upwards, between the thyreoid and cricoid cartilages, and must be preserved.

Upon the posterior aspect of the broad lamina of the cricoid cartilage the dissector will now note the two posterior crico-arytænoid muscles, and the attachment of the tendinous band through which the longitudinal fibres of the œsophagus are fixed to the cricoid cartilage. The band takes origin from the prominent median ridge on the posterior aspect of the cricoid cartilage. On the posterior surface of the arytænoid cartilages,

and bridging across the interval between them, are the transverse and oblique parts of the arytænoid muscle. Especial care must be taken whilst that muscle is being cleaned, in order that the connections of the superficial decussating fibres may be ascertained fully.

The lateral layer of the left ary-epiglottic fold of mucous membrane should now be cautiously removed, to expose the ary-epiglottic muscle, the cuneiform cartilage, and the corniculate cartilage of that side. This is perhaps the most difficult part of the dissection, because the dissector has to establish the continuity of the sparse fibres, which compose the pale ary-epiglottic muscle, with the decussating fibres of the arytænoid muscle (Fig. 123).

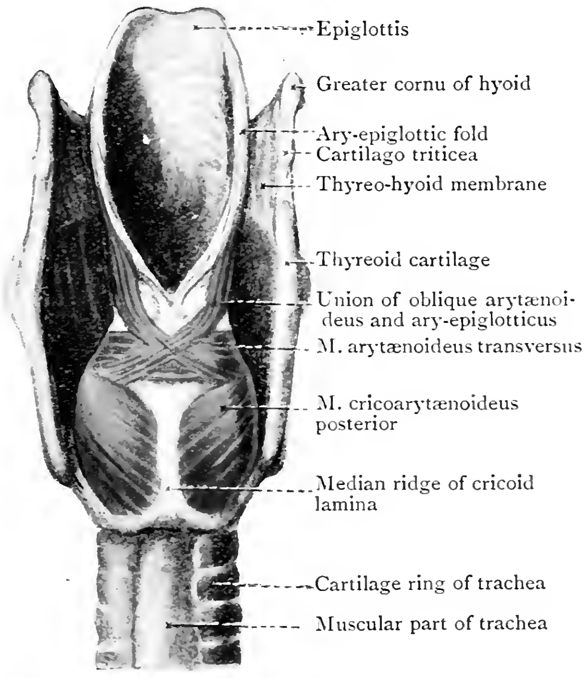

FIG. 123.—Muscles of the Posterior Aspect of the Larynx.

Musculus Crico-arytænoideus Posterior.—Each posterior crico-arytænoid muscle is somewhat fan-shaped (Fig. 123). It springs, by a broad origin, from the depression which marks the posterior surface of the cricoid cartilage, on the corresponding side of the median ridge, and its fibres converge to be inserted into the posterior surface of the *muscular process* or projecting lateral angle of the base of the arytænoid cartilage.

As the fibres pass from origin to insertion, they run with different degrees of obliquity. The uppermost fibres are

short and nearly horizontal; the intermediate fibres are the longest, and are very oblique; whilst the lowest fibres are almost vertical in their direction. The posterior crico-arytænoid muscles are abductors of the vocal folds. They are supplied by the inferior laryngeal nerves.

Musculus Arytænoideus.—The arytænoid muscle consists of two portions—a superficial part, termed the *arytænoideus obliquus*, and a deeper layer, called the *arytænoideus transversus*.

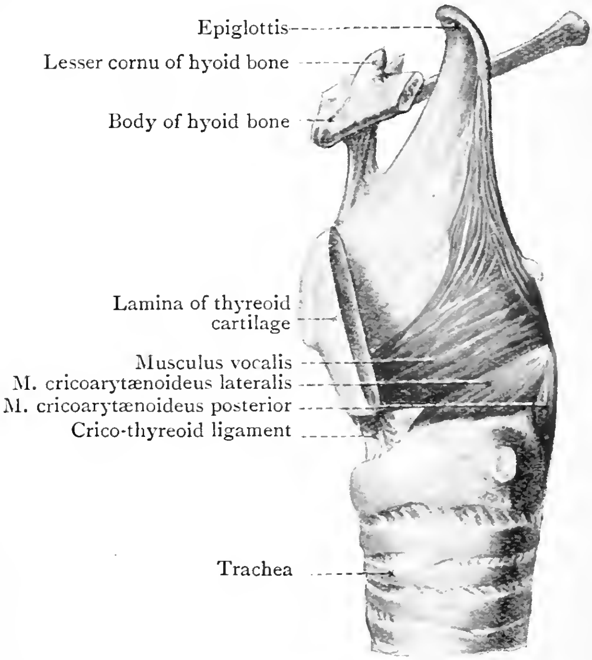

FIG. 124.—Side view of the Muscles of the Larynx. The fibres passing backwards and upwards from the upper border of the musculus vocalis are the fibres of the thyreo-epiglotticus. They blend above with the ary-epiglotticus.

The *arytænoideus obliquus* is composed of two bundles of muscular fibres, each of which springs from the posterior aspect of the muscular process of the corresponding arytænoid cartilage (Fig. 123). From those points the two fleshy slips proceed upwards and medially, and cross each other in the median plane like the limbs of the letter X. Some of the fibres are inserted into the summit of the arytænoid cartilage of the opposite side, but the greater proportion are prolonged, round the base of the corniculate cartilage,

into the ary-epiglottic fold. There they receive the name of the *ary-epiglotticus muscle*, and, as they approach the epiglottis, they are joined by the fibres of the thyreo-epiglotticus muscle. The oblique arytænoid muscles may be considered as constituting a weak sphincter muscle for the superior aperture of the larynx. Each bundle starts from the base of one of the arytænoid cartilages and is prolonged into the ary-epiglottic fold of the opposite side, and onwards, along the fold, to the margin of the epiglottis.

The *arytænoideus transversus* is an unpaired muscle. It is composed of transverse fibres which bridge across the interval between the two arytænoid cartilages and are attached to the posterior aspect of the lateral border of each arytænoid cartilage. Many of the fibres turn round the arytænoid cartilage and become continuous, on each side, with the fibres of the thyreo-arytænoid muscle. Both groups of fibres are supplied by the inferior laryngeal nerves. The oblique fibres form a weak sphincter of the superior laryngeal aperture. The transverse fibres adduct the arytænoid cartilages and abduct the vocal folds.

Dissection.—The further dissection of the laryngeal muscles should be confined to the left side of the larynx. The right side should be reserved for the study of the nerves and vessels. Place the larynx on its right side, and, having fixed it in that position, remove the left crico-thyreoid muscle. The left lateral part of the thyreo-hyoid membrane should next be divided, and the left inferior cornu of the thyreoid cartilage disarticulated from its facet on the side of the cricoid cartilage. An incision should now be made through the left lamina of the thyreoid cartilage, a short distance to the left side of the median plane, and the detached piece must be carefully removed. Three muscles are now exposed, and must be cleaned. They are named, from below upwards :—

1. The lateral crico-arytænoid.
2. The thyreo-arytænoid.
3. The thyreo-epiglotticus.

Musculus Crico-arytænoideus Lateralis.—Each lateral crico-arytænoid muscle is triangular in form, and smaller than the posterior crico-arytænoid (Fig. 124). It springs from the upper border of the arch of the cricoid cartilage, extending to the facet on the lamina which supports the base of the arytænoid cartilage; a few of its fibres take origin from the conus elasticus also. From its lower attachment its fibres run backwards and upwards, and converge

to be inserted into the anterior surface of the processus muscularis of the arytænoid cartilage. The superficial or lateral surface of the muscle is covered by the lamina of the thyreoid cartilage and the upper part of the crico-thyreoid muscle; its deep surface is applied to the conus elasticus. The lateral crico-arytænoid muscles are supplied by the inferior laryngeal nerves. They are adductors of the vocal folds.

Musculus Thyreo-arytænoideus (O.T. **Thyro-arytenoideus Externus**).—Each thyreo-arytænoid muscle springs from the angle of union of the two laminæ of the thyreoid cartilage, in close association with the vocalis. Its fibres pass backwards, and are inserted into the lateral surface of the arytænoid cartilage. It protracts the arytænoid cartilage, and adducts and relaxes the vocal fold. It is supplied by the inferior laryngeal nerve.

> ***Dissection.***—The lateral crico-arytænoid muscle should now be carefully removed, and at the same time the dissector should endeavour to disengage the fibres of the thyreo-arytænoideus from the deeper musculus vocalis, in order that the relation of the vocalis to the vocal ligament may be studied. Finally, remove the musculus vocalis. When the muscles are removed, the lateral surface of the conus elasticus, the vocal ligament, and the wall of the laryngeal ventricle will be displayed. By carefully dissecting between the two layers of mucous membrane which form the ventricular fold, the dissector may find the weak ventricular ligament, which supports the fold, as well as a number of racemose glands which lie in relation to it.

Musculus Thyreo-epiglotticus.—Each thyreo-epiglottic muscle springs from the thyreoid cartilage, immediately above the corresponding musculus vocalis, with the upper border of which it is more or less blended. Its fibres run backwards and upwards, into the ary-epiglottic fold, where they blend with the ary-epiglotticus, and they are inserted into the edge of the lower half of the epiglottis. The thyreo-epiglottic muscles depress the epiglottis. They are supplied by the inferior laryngeal nerves.

Musculus Vocalis.—Each musculus vocalis is a sheet of muscular fibres which springs, anteriorly, from the angle of union of the two laminæ of the thyreoid cartilage. It runs backwards, along the ligamentum vocale and the upper part of the conus elasticus, and is inserted into the lateral surface of the vocal process and the anterior surface of the body of the arytænoid cartilage. Its lower fibres blend with the

upper margin of the lateral crico-arytænoid muscle, and the medial fibres, which run along and to a certain extent are attached to the ligamentum vocale,[1] form a bundle, triangular in frontal section, to which the term internal thyro-arytænoid muscle was formerly applied. The vocalis muscles protract the arytænoid cartilages, and adduct and relax the vocal folds. They are supplied by the inferior laryngeal nerves.

Ligamentum Vocale.—There are two vocal ligaments, right and left. Each is the thickened free upper border of

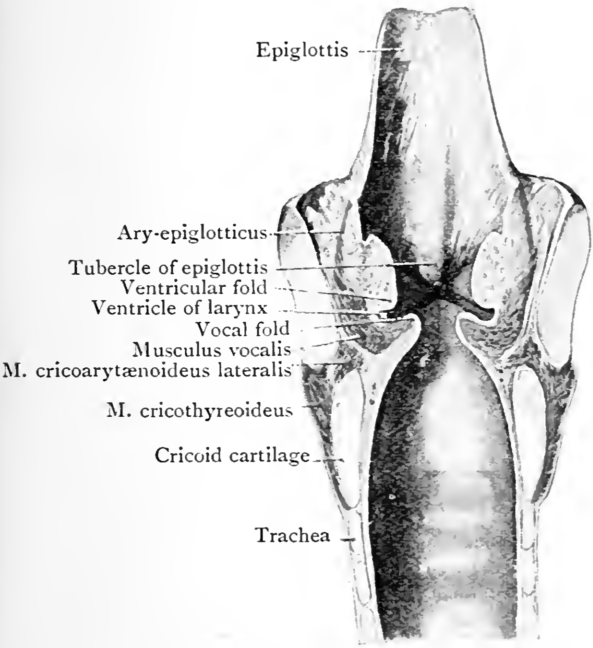

FIG. 125.—Frontal section of Larynx, showing Muscles.

the corresponding lateral part of the conus elasticus, and it constitutes the support of the vocal fold. *Anteriorly*, it is attached, close to its fellow of the opposite side, to the middle of the angular depression between the two laminæ of the thyreoid cartilage. *Posteriorly*, it is attached to the tip and upper border of the processus vocalis, which projects forwards from the base of the arytænoid cartilage. The vocal ligament is composed of yellow elastic fibres. Its medial border is sharp and free, and is clothed with mucous membrane,

[1] The fibres which are attached to the ligamentum vocale are called collectively the *ary-vocalis muscle*.

which is thin and firmly bound down to the ligament. Embedded in its anterior extremity there is a minute nodule of condensed elastic tissue, called the *sesamoid cartilage*.

Dissection.—By removing the mucous membrane in the region of the rima glottidis and the laryngeal ventricle a good view of the parts which bound the rima will be obtained—viz., *anteriorly*, the angle of the thyreoid cartilage; *posteriorly*, the arytænoideus transversus muscle; *on each side*, the vocal ligament, the processus vocalis, and the medial surface of the arytænoid cartilage (p. 343). They are all clothed with the lining mucous membrane of the larynx.

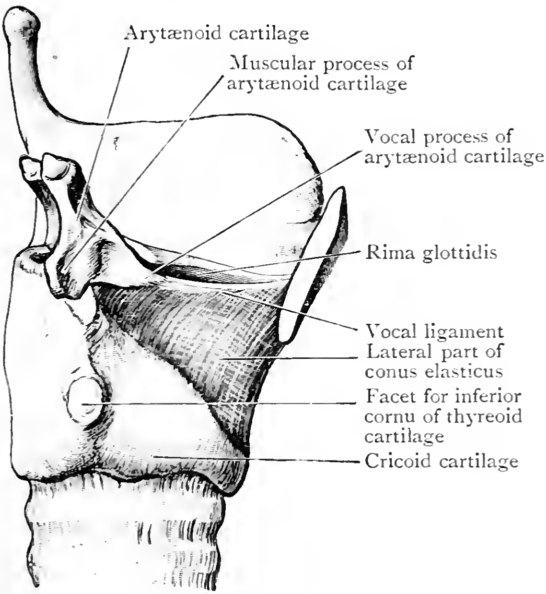

FIG. 126.—Conus elasticus. The right lamina of the thyreoid cartilage, etc., have been removed.

Ligamentum Ventriculare.—The feeble ventricular ligaments support the ventricular folds. Each is weak and indefinite, but somewhat longer than the corresponding vocal ligament. Anteriorly, each ventricular ligament is attached to the angular depression between the two laminæ of the thyreoid cartilage, above the vocal fold and immediately below the attachment of the thyreo-epiglottic ligament; and it extends backwards to a tubercle on the lateral surface of the arytænoid cartilage above the processus vocalis. It is composed of connective tissue and elastic fibres, which are continuous with the fibrous tissue in the ary-epiglottic fold.

Dissection.—Remove the remains of the ary-epiglottic fold, the ventricular and the vocal folds, and the lateral part of the conus elasticus, on the left side of the larynx, but be careful not to injure the arytænoid cartilage or the corniculate cartilage. If the cuneiform cartilage is present in the ary-epiglottic fold it should be detached and preserved. By this dissection a good view of the side wall of the laryngeal cavity can be obtained.

The undissected vocal fold of the right side should be examined again ; the laryngeal ventricle and appendix should be explored, and their precise connections and extent determined. When the dissector has satisfied himself about those points he can proceed to display the vessels and nerves of the larynx. The superior laryngeal artery and the internal laryngeal nerve reach the pharynx by piercing the lateral thin part of the thyreo-hyoid membrane, and they descend, along the lateral wall of the recessus piriformis, to the larynx. By applying traction to the nerve, and at the same time dividing the mucous membrane upon the medial surface of the thyreo-hyoid membrane, the dissector can easily find the nerve and artery. As the branches into which they divide are followed, the mucous membrane must be gradually removed from the wall of the larynx. The inferior laryngeal artery and nerve enter from below and proceed upwards, under cover of the lamina of the thyreoid cartilage. They can be satisfactorily displayed only by the removal of that piece of cartilage, but the dissector is not recommended to adopt the method suggested unless another larynx is available for the examination of the cartilages and joints. If the thyreoid cartilage is drawn laterally the more important branches can be studied.

Ramus Internus Nervi Laryngei Superioris.—In the dissection of the neck the internal laryngeal nerve of each side was seen springing from the superior laryngeal branch of the corresponding vagus. It is a sensory nerve, and its branches are distributed chiefly to the mucous membrane of the larynx. After piercing of the thyreo-hyoid membrane, it divides into three branches. The *uppermost* of the three sends filaments to the ary-epiglottic fold, to the mucous membrane which covers the epiglottis, to the folds anterior to it, and to the lower and middle part of the back of the tongue. The twigs which go to the epiglottis ramify on its posterior surface, but many of them pierce the cartilage to reach the mucous membrane on its anterior surface. The *middle branch* of the internal laryngeal nerve breaks up into filaments which are given to the mucous membrane lining the side wall of the larynx. The *lowest branch* descends and gives filaments to the mucous membrane on the lateral and posterior aspects of the arytænoid and cricoid cartilages. It also gives off a fairly large twig which runs downwards upon the posterior aspect of the cricoid cartilage to join the laryngeal branch of the recurrent nerve.

Nervus Recurrens.—Each recurrent nerve has previously been seen arising from the corresponding vagus, and it has been traced, in the neck, up to the point where it disappears under cover of the lower border of the inferior constrictor muscle and becomes the *inferior laryngeal nerve*, which ascends

upon the lateral aspect of the cricoid cartilage, immediately posterior to the crico-thyreoid joint. There it is joined by the communicating twig from the internal laryngeal nerve, and almost immediately afterwards it divides into two branches. The *larger* of the two proceeds upwards, under cover of the lamina of the thyreoid cartilage, and breaks up into filaments which supply the lateral crico-arytænoid, the thyreo-arytænoid, the vocalis and the thyreo-epiglottic muscles; the *smaller* or *posterior branch* inclines upwards and backwards, upon the posterior aspect of the cricoid cartilage, and under cover of the posterior crico-arytænoid muscle. It supplies twigs to that muscle, and is then continued onwards to end in the arytænoid muscles.

The inferior laryngeal nerve is, therefore, the motor nerve of the larynx. It supplies all the muscles, with the exception of the crico-thyreoid, which obtains its nerve-supply from the external laryngeal. The inferior laryngeal nerve, however, contains a few sensory fibres also. Those it gives to the mucous membrane of the larynx below the rima glottidis.

Laryngeal Arteries.—The *superior laryngeal artery*, a branch of the superior thyreoid, accompanies the internal laryngeal nerve; the *inferior laryngeal artery*, which springs from the inferior thyreoid, accompanies the inferior laryngeal nerve. The two vessels ramify in the laryngeal wall and supply the mucous membrane, glands, and muscles.

Laryngeal Cartilages and Joints.—The cartilages which constitute the skeleton of the larynx and give support to its wall are the following:—

1. Thyreoid, 2. Cricoid, 3. Cartilage of the epiglottis,	single.	4. Arytænoid, 5. Corniculate, 6. Cuneiform,	paired.

They are connected by certain ligaments.

> ***Dissection.***—The mucous membrane and muscles must be carefully removed from the cartilages, and the ligaments must be defined. Exercise great caution while cleaning the arytænoid cartilages and the corniculate cartilages, in order that the latter may not be injured.

Cartilago Epiglottica.—The epiglottic cartilage is a thin, leaf-like lamina of yellow fibro-cartilage which is placed posterior to the tongue and the body of the hyoid bone, and anterior to the upper aperture of the larynx. When divested of the

mucous membrane which covers it posteriorly and also, to some extent, anteriorly, the epiglottic cartilage has the form of an obovate leaf; it is indented by pits, and shows numerous perforations. In the pits glands are lodged, and through the foramina vessels and, in some cases, nerves pass. The broad end of the cartilage is directed upwards, and is free; its lateral margins are to a large extent enclosed within the ary-epiglottic folds. The anterior surface is free only in its upper part. That part is covered with mucous membrane, and looks towards the tongue. The posterior surface is covered, throughout its whole extent, with the mucous membrane of the larynx. The pointed lower end of the cartilage is called *the petiolus*, and is connected by a stout fibrous band, termed the thyreo-epiglottic ligament, to the angle between the laminæ of the thyreoid cartilage.

Epiglottic Ligaments. — The epiglottis is bound by ligaments to the base of the tongue, to the side wall of the pharynx, to the hyoid bone, and to the thyreoid cartilage. The *glosso-epiglottic fold* and the two *pharyngo-epiglottic folds* have been studied already. In each there is a small quantity of elastic tissue. The *hyo-epiglottic ligament* is a short, broad elastic band which connects the anterior face of the epiglottis to the upper border of the body of the hyoid bone. The *thyreo-epiglottic ligament* is strong, elastic, and thick. It proceeds downwards, from the lower pointed extremity of the epiglottis, and is attached to the angular depression between the two laminæ of the thyreoid cartilage, below the median notch.

The triangular interval which is left between the lower part of the cartilage of the epiglottis and the median part of the thyreo-hyoid membrane contains a pad of soft fat, and it is imperfectly closed above by the hyo-epiglottic ligament.

Cartilago Thyreoidea.—The thyreoid cartilage is the largest of the laryngeal cartilages. It is composed of two broad and somewhat quadrilateral plates, termed the *laminæ*, which meet anteriorly at an angle, and become fused along the median plane. Posteriorly, the laminæ diverge from each other and enclose a wide angular space. The *anterior borders* of the laminæ are fused only in their lower parts. Above, they are separated by a deep, narrow V-shaped notch, called the *incisura thyreoidea superior*. In the adult male, the angle formed by the meeting of the anterior borders of the two laminæ, especially in the upper part, is very projecting; and, with the

margins of the superior thyreoid notch, which lies above, it constitutes a marked subcutaneous prominence in the neck, which receives the name of the *laryngeal prominence* (O.T. *pomum Adami*). The *posterior border* of each lamina is thick and rounded, and is prolonged, beyond the superior and inferior borders of the lamina, in the form of two slender cylindrical processes, termed the cornua. The *superior cornu*,

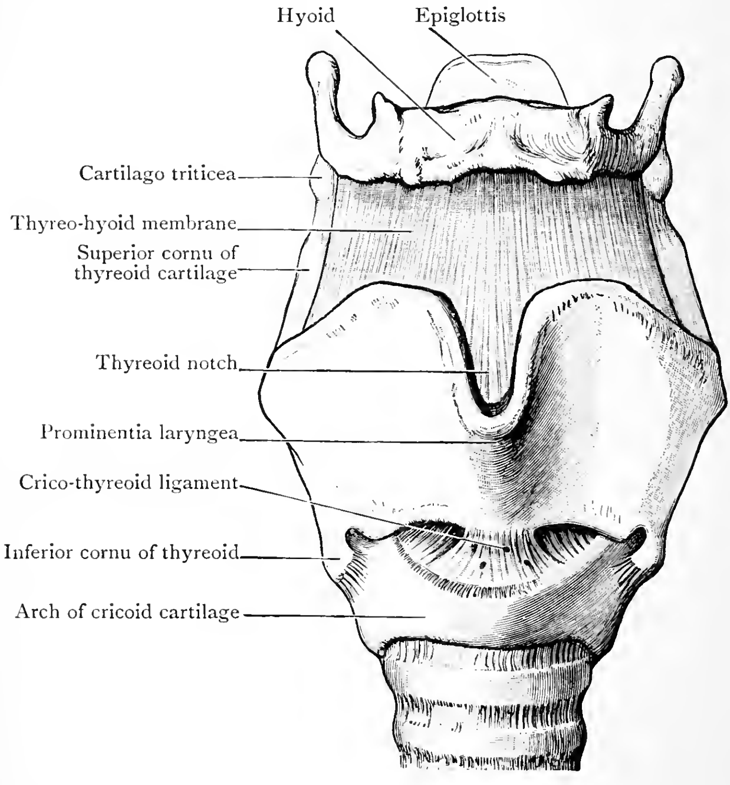

FIG. 127.—Anterior aspect of the Cartilages and Ligaments of Larynx.

longer than the inferior cornu, gives attachment to the lateral thyreo-hyoid ligament. The shorter, stronger *inferior cornu* curves slightly medially. On the medial aspect of its tip there is a facet which articulates with the side of the cricoid cartilage. The *superior border* of the lamina is for the most part slightly convex, and anteriorly it dips down to become continuous with the margin of the superior thyreoid notch. The *inferior border* is to all intents and purposes horizontal, but it is divided by a projection, termed the *inferior tubercle*, into

a short posterior part and a longer anterior part. The *lateral surface* of the lamina is relatively flat. Immediately below the posterior part of the upper border, and anterior to the root of the superior cornu, there is a distinct prominence called the *superior tubercle.* From that point an oblique ridge descends towards the inferior tubercle on the lower border of the lamina. The ridge gives attachment to the sterno-thyreoid, thyreo-hyoid and the inferior constrictor muscles, and divides the lateral surface of the lamina into an anterior and a posterior part. To the posterior part, which is much the smaller of the two, is attached the inferior constrictor muscle of the pharynx. The *medial surface* of the lamina is smooth and slightly concave. To the angular depression between the two laminæ are attached the thyreo-epiglottic ligament, the ventricular and the vocal ligaments.

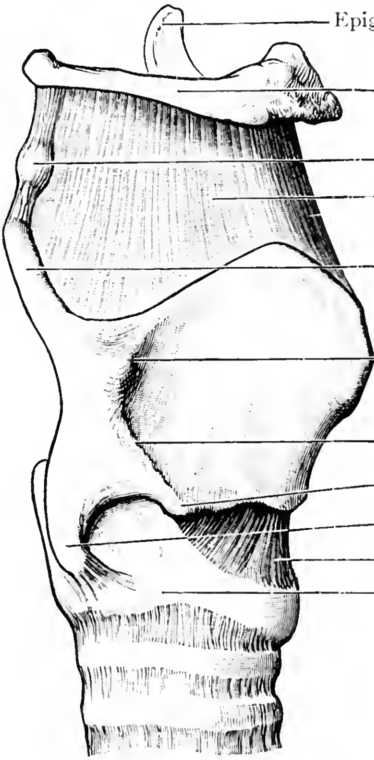

FIG. 128.—Profile view of Cartilages and Ligaments of Larynx.

Crico-thyreoid Joints.—The articulation, on each side, between the tip of the inferior cornu of the thyreoid cartilage and the side of the cricoid cartilage, belongs to the diarthrodial variety. The opposed surfaces are surrounded by an articular capsule which is lined with a synovial stratum. The movements which take place at the joints are of a twofold character—viz., (1) gliding; (2) rotatory. In the first case the cricoid facets glide upon the thyreoid surfaces in various directions. The rotatory movement is one in which the cricoid cartilage rotates around a transverse axis which

passes through the centres of the two joints. Each articular capsule is strengthened by stout bands on the posterior aspect of the joint (Fig. 129).

Dissection.—Divide the ligaments which surround the crico-thyreoid joint, and remove the thyreoid cartilage.

Cartilago Cricoidea.—The cricoid cartilage is shaped like

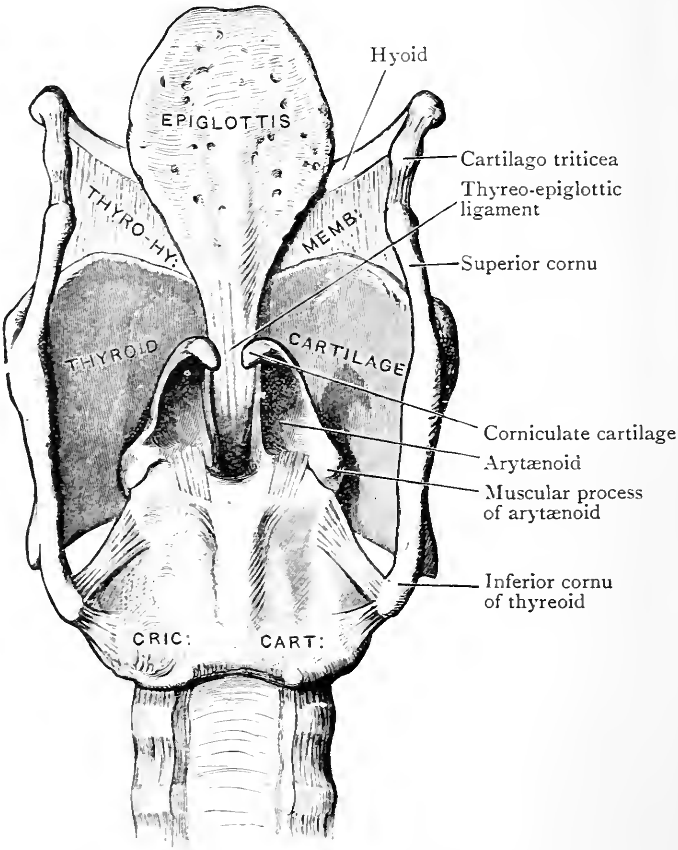

FIG. 129.—Posterior aspect of Cartilages and Ligaments of Larynx.

a signet ring. The broad, posterior part, called *the lamina*, is somewhat quadrangular in form. Its superior border presents a faintly marked median notch, and on each side of the notch there is an oval, convex facet which articulates with the base of the arytænoid cartilage. The posterior surface of the lamina is divided, by an elevated median ridge, into two slightly hollowed-out areas which give attachment to the posterior crico-arytænoid muscles. The median ridge

itself gives origin to a tendinous band which proceeds upwards from the longitudinal fibres of the œsophagus. The anterior part of the cricoid cartilage is the *arch*, and it narrows anteriorly. The lower border of the arch is horizontal, and is connected to the first tracheal ring by membrane, the *crico-tracheal ligament*. The upper border is connected, anteriorly, to the lower border of the thyreoid cartilage by the crico-thyreoid ligament. Posteriorly, the upper border rapidly ascends, and to it is attached the corresponding half of the conus elasticus. Upon the posterior part of the lateral surface of the cricoid cartilage there is a circular, slightly elevated, convex facet, which looks laterally and upwards, for articulation with the inferior cornu of the thyreoid cartilage. Internally, the cricoid cartilage is lined with mucous membrane.

The narrow band-like part of the anterior arch of the cricoid cartilage lies below the lower border of the thyreoid cartilage, whilst the lamina is received into the interval between the posterior portions of the laminæ of the thyreoid cartilage.

Cartilagines Corniculatæ.—Before proceeding to the study of the arytænoid cartilages the dissector should examine the corniculate cartilages and the manner in which they are held in position. They are two minute pyramidal nodules of yellow elastic cartilage which are placed on the summits of the arytænoid cartilages, and are directed backwards and medially. Each corniculate cartilage is enclosed within the corresponding ary-epiglottic fold of mucous membrane, and is joined to the apex of the arytænoid cartilage by a synchondrodial joint.

Cartilagines Arytænoideæ.—Commence the study of the arytænoid cartilages by noting their relation to one another and to the cricoid cartilage. Then remove one cartilage and examine its surfaces and borders. Retain the other cartilage in position for the purpose of examining the crico-arytænoid joint and the movements which can be performed at that articulation.

The *arytænoid cartilages* are pyramidal in form, and they surmount the upper border of the lamina of the cricoid cartilage. The *apex* of each is directed upwards, and it curves backwards and medially. It supports the corniculate cartilage. Of the three surfaces, one looks medially, towards

the corresponding surface of the opposite cartilage, from which it is separated by the rima glottidis; another looks backwards; whilst the third is directed antero-laterally. The *medial surface* is narrow, vertical and even, and is clothed with mucous membrane. The *posterior surface* is concave; it lodges and gives attachment to the arytænoideus transversus muscle. The *antero-lateral surface* is the most extensive of the three, and is uneven for muscular and ligamentous attachments. Upon that aspect of the arytænoid cartilage the musculus vocalis and the thyreo-arytænoid muscle are inserted. The surfaces of the arytænoid cartilage are separated by three borders, viz., an anterior, a posterior, and a lateral. The *lateral border* is the longest, and, at the base of the cartilage, it bulges backwards and laterally in the form of a stout, prominent angle or process, termed the *processus muscularis.* It gives attachment, anteriorly, to the crico-arytænoideus lateralis muscle; and, posteriorly, to the crico-arytænoideus posterior. The *anterior border* of the arytænoid cartilage is prolonged into the projecting anterior angle of the base, which is called the *processus vocalis.* The vocal process is sharp and pointed, and gives attachment to the vocal ligament (O.T. true vocal cord). The *base* of the arytænoid cartilage presents an elongated concave facet, on its under aspect, for articulation with the upper border of the lamina of the cricoid cartilage.

Crico-arytænoid Joints.—The crico-arytænoid joints are of the diarthrodial variety. Each has a distinct joint cavity, surrounded by an articular capsule, which is lined with a synovial stratum. The cricoid articular surface is convex; that of the arytænoid is concave; both are elongated in form, but they are placed in relation to each other so that the long axis of the one intersects or crosses that of the other, and in no position of the joint do the two surfaces accurately coincide. The movements allowed at the joints, as the dissector can readily determine, are of a twofold kind—(1) *gliding*, by which the arytænoid is carried medially or laterally, or, in other words, a movement by which the arytænoid advances towards or retreats from its fellow; (2) *rotatory*, by which the arytænoid cartilage rotates round a vertical axis. By that movement the vocal process is swung laterally or medially, so as to open or close the rima glottidis.

The dissector should note that the capsule of each joint

is strengthened posteriorly by a strong band which restricts movement of the arytænoid cartilage.

Cartilagines Cuneiformes.—The cuneiform cartilages are two little rod-shaped nodules of yellow elastic cartilage, which are placed one in each ary-epiglottic fold near its posterior end (Fig. 120). They are not always present.

Actions of the Laryngeal Muscles.—The dissector should now consider the manner in which the muscles of the larynx operate upon the vocal folds, in the production of the voice. *Tension* of the vocal folds is produced by the contraction of the *crico-thyreoid muscles.* The straight parts of the muscles pull the upper border of the cricoid cartilage upwards, whilst the oblique portions, through their insertions into the inferior cornua, draw the cricoid cartilage backwards, thereby increasing the distance between the angle of the thyreoid cartilage and the vocal processes of the arytænoid cartilages. When the crico-thyreoid muscles cease to contract, the relaxation of the vocal folds is brought about by the elasticity of the ligaments. The vocalis and the thyreo-arytænoideus must be regarded as antagonistic to the crico-thyreoid muscles. When they contract they approximate the angle of the thyreoid cartilage to the arytænoid cartilages, and still further relax the vocal folds, and when they cease to act, the elastic ligaments of the larynx again bring about a state of equilibrium.

The *width of the rima glottidis* is regulated by the arytænoideus muscle, which draws together the arytænoid cartilages. The lateral and posterior crico-arytænoid muscles also modify the width of the rima glottidis. When they act together they assist the arytænoid muscle in closing the rima glottidis, but when they act independently they are antagonistic muscles. Thus the *crico-arytænoidei posteriores*, by drawing the muscular processes of the arytænoid cartilages backwards and laterally, swing the processus vocales and the vocal folds laterally, and thus open the rima. The *crico-arytænoidei laterales* act in exactly the opposite manner. By drawing the muscular processes in an opposite direction they close the rima.

But the muscles of the larynx have another function to perform besides that of vocalisation. It was formerly thought that the superior aperture of the larynx was closed, during deglutition, by the folding back of the epiglottis; that, in fact, the epiglottis, during the passage of the bolus of food,

was applied like a lid over the entrance to the vestibule of the larynx. The investigations of Anderson Stuart have shown that the superior aperture of the larynx is closed during swallowing by the close apposition and the forward projection of the two arytænoid cartilages, which are forced against the tubercle of the epiglottis. The muscles chiefly concerned in that movement are the thyreo-arytænoid muscles and the transverse arytænoid muscle. They form, collectively, a true sphincter vestibuli. The ary-epiglottic muscles also assist in the closure.

THE TONGUE.

The tongue is a mobile organ which lies on the floor of the mouth. It consists of a mass of muscles covered with mucous membrane, and interspaced with a small amount of fat and some glands. It is closely associated with the functions of taste, mastication, deglutition, and articulation.

It has the form of a shoe turned upside down, and through the opening of the shoe, which corresponds with the *root* of the tongue, pass the muscles which connect the tongue with the hyoid bone and the mandible (Figs. 131, 133).

The free part of the tongue possesses a lower surface, and a dorsum. The dorsum is separable into an oral or upper portion, which is also called the upper surface and which terminates anteriorly at the *apex*, and a posterior or pharyngeal portion, which is also called the *base*. The *lower surface*, which is smooth, rests on the floor of the mouth. The *upper surface* is rough; it lies in relation to the roof of the mouth (Figs. 72, 110, and 114); the *apex* touches the incisor teeth, and the *base* forms a part of the anterior wall of the pharynx (Fig. 110). The upper border of the base is continuous with the upper surface and it forms the lower boundary of the isthmus of the fauces. The upper surface is separated from the lower surface, on each side, by a distinct but rounded border (Fig. 134).

The Mucous Membrane.—The tongue is covered with mucous membrane, which is continuous with the general lining of the oral cavity and pharynx, but which presents very different appearances on different areas of the tongue. In the middle line of the tongue, at the junction of the upper surface with the pharyngeal surface, there is a median pit in

the mucous membrane called the *foramen cæcum.* From the foramen cæcum the two limbs of a V-shaped sulcus diverge antero-laterally, to terminate on the margins of the tongue at the attachments of the glosso-palatine arches. The V-shaped sulcus is called the *sulcus terminalis*; it is an indication of the double origin of the tongue; the part anterior to the sulcus, which lies in the floor of the mouth, and is, therefore, called the *oral part*, is developed from the mandibular arches and the associated *tuberculum impar* of the embryo; the

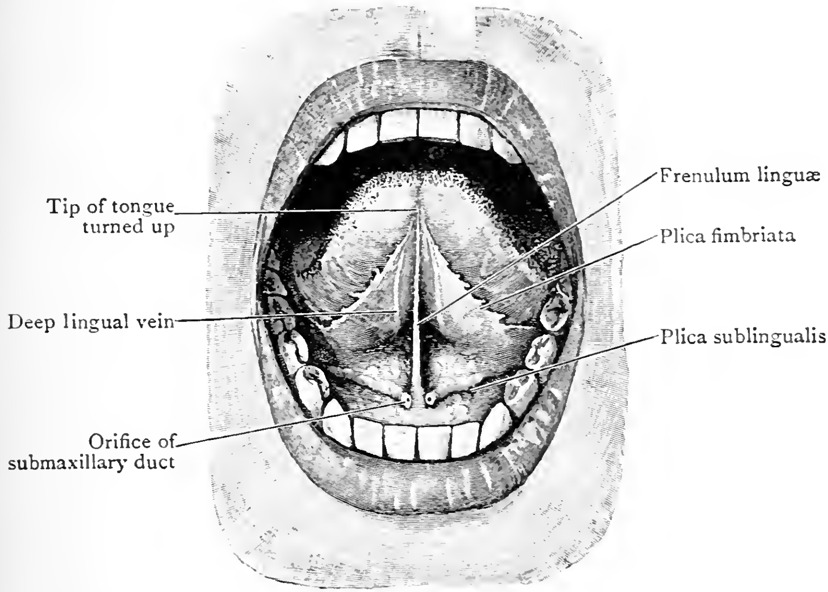

FIG. 130.—The Sublingual Region in the interior of the mouth.

posterior or *pharyngeal part* is developed from the second pair of visceral arches.

The mucous membrane of the pharyngeal surface lies in relation with the soft palate and the posterior wall of the pharynx, and it is continuous laterally with the mucous membrane of the palatine tonsils, and, posteriorly, with that of the epiglottis. Where it covers the pharyngeal surface of the tongue it is smooth and glossy and it has no projecting papillæ, but it is studded with low elevations, produced by masses of lymph follicles embedded in the submucous tissue, and in each elevation there is usually a small central pit. As the mucous membrane passes from the tongue to the epiglottis it is raised into a small median fold called the glosso-epiglottic fold.

Anterior to the foramen cæcum and sulcus terminalis the mucous membrane which covers the dorsum, sides, and tip of the oral part of the tongue is studded with papillæ of different kinds. As these are individually visible to the naked eye the mucous membrane presents a very characteristic appearance. Further, a median groove or sulcus extends backwards from the tip of the tongue to the foramen cæcum, and divides the anterior two-thirds of the dorsum into two halves.

On the inferior surface of the tongue the mucous membrane is smooth and comparatively thin. In the median plane it forms the *frenulum linguæ*, which has been studied at an earlier stage. On each side of the median line the deep lingual vein may be noticed, in the living subject, extending forwards towards the tip. To the lateral side of the vein, and, therefore, somewhat nearer the border of the tongue, is a delicate and feebly marked ridge of mucous membrane, from the free border of which a row of fringe-like processes or fimbriæ project. It is termed the *plica fimbriata*; as it extends forwards, towards the tip of the tongue, it inclines towards the median plane. On the side of the tongue, immediately anterior to the lingual attachment of the glosso-palatine arches, five short vertical fissures in the mucous membrane, separated by intervening folds, may be noticed. The folds are called the *papillæ foliatæ*. They are the representatives of leaf-like folds of the mucous membrane which are much more highly developed in certain of the lower animals (hare and rabbit), and which are specially concerned in receiving the impressions of taste.

Papillæ Linguales.—The papillæ are of four kinds, and differ in size, shape, and in the position they occupy on the surface of the tongue. They are termed the vallate, the fungiform, the conical, and the filiform.

Papillæ Vallatæ.—The vallate papillæ (O.T. circumvallate), seven to twelve in number, are the largest, and are placed immediately anterior to the sulcus terminalis, in two rows which diverge from each other in an antero-lateral direction, like the two limbs of the letter V. The foramen cæcum lies immediately posterior to the median vallate papilla, which forms the apex of the V. In form, a vallate papilla is broad and somewhat cylindrical, slightly narrower at its attached end than at its free extremity, and it is sunk in a pit. It is thus surrounded by a deep trench, the outer wall of

which, termed the *vallum*, is slightly raised beyond the general surface of the mucous membrane, and forms an annular elevation which encircles the free extremity or summit of the papilla.

Papillæ Fungiformes.—The fungiform papillæ are much smaller, but are present in much greater numbers. They are found chiefly on the tip and sides of the tongue, but they are scattered, at irregular intervals, over the upper surface also. Each papilla presents a large, full, rounded, knob-like extremity, while it is greatly constricted at the point where it

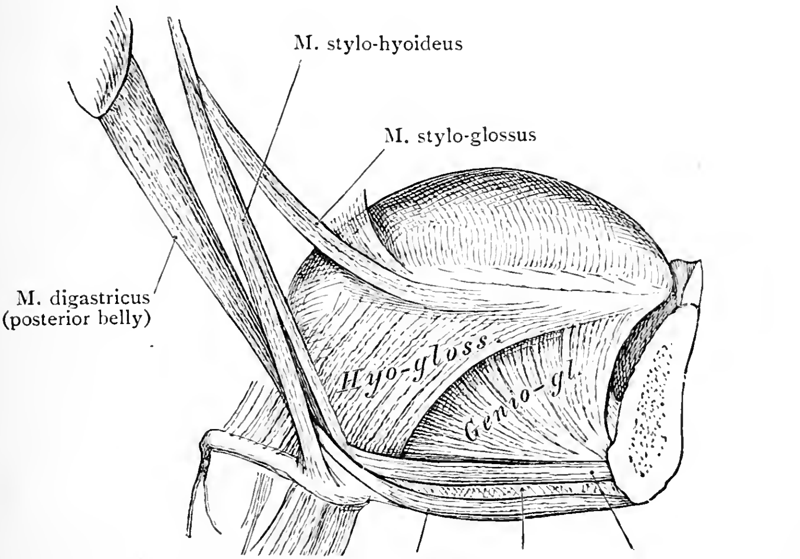

FIG. 131.—Muscles of the Tongue. (From Gegenbaur.)

springs from the mucous surface. In the living tongue the fungiform papillæ are distinguished by their bright red colour.

Papillæ Conicæ.—The conical papillæ are present in very large numbers. They are smaller than the fungiform variety, and although they are quite visible to the naked eye they can be more conveniently studied with an ordinary pocket lens. They are minute conical projections which taper towards their free extremities, and they occupy the dorsum and sides of the tongue, anterior to the sulcus terminalis. They are arranged in parallel rows which are placed close together. On the posterior part of the upper surface the rows diverge from the median sulcus in an antero-lateral

direction. Towards the tip of the tongue the rows of conical papillæ become more or less transverse in direction, and on the sides of the tongue they are arranged perpendicularly.

Papillæ Filiformes.—The filiform papillæ are similar in general characters to the conical papillæ, but the epithelial cap at the apex of the cone is broken up into thread-like processes.

Muscles of the Tongue.—The tongue is composed almost entirely of muscular fibres, with some adipose and glandular and fibrous tissue intermixed. It is divided into two halves by a median septum, and the muscles in connection with each

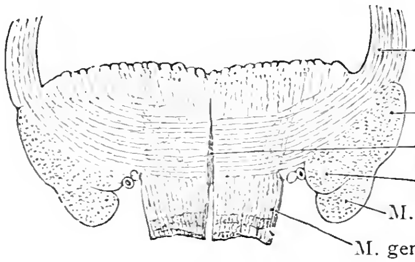

FIG. 132.—Transverse section through the posterior part of the Tongue. (From Gegenbaur.)

half consist of an intrinsic and an extrinsic group. They are as follows:—

Extrinsic Muscles,
1. Genio-glossus.
2. Hyo-glossus.
3. Chondro-glossus.
4. Stylo-glossus.
5. Glosso-palatinus.

Intrinsic Muscles,
1. Superior longitudinal.
2. Inferior longitudinal.
3. Vertical.
4. Transverse.

The *extrinsic muscles* take origin from parts outside the tongue, and thus are capable not only of giving rise to changes in the form of the organ, but also of producing changes in its position. The *intrinsic muscles*, which are placed entirely within the substance of the tongue, are, for the most part, capable of giving rise to alterations in its form only.

Dissection.—With the exception of the chondro-glossus, the extrinsic muscles have been studied already, but the dissector should now take the opportunity of examining more fully their insertions, and the manner in which their fibres are related to one another and to those of the intrinsic muscles. To display

the details, carefully reflect the mucous membrane from the right half of the tongue, and follow the muscles into that side of the organ. At the same time the lingual nerve and the profunda linguæ artery should be preserved. On the under surface of the tongue, near the tip, the removal of the mucous membrane will expose a group of glands, aggregated together so as to form a small oval mass on each side of the median plane. The mass of glands is known as the *apical gland* or the *gland of Nühn*.

The *stylo-glossus* will be seen running along the side of the tongue to the tip, where the muscles of opposite sides become, to a certain extent, continuous. The *hyo-glossus* extends upwards to the side of the tongue, and its fibres pass, for the most part, under cover of those of the stylo-glossus to reach the dorsum, over the posterior part of which they spread out, beneath the mucous membrane. The *genio-glossus* sends

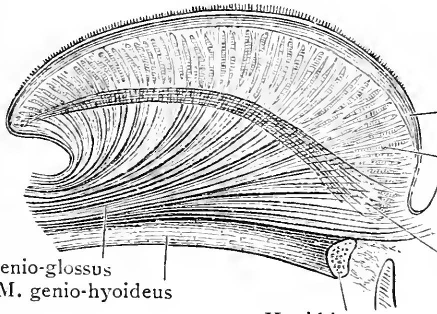

FIG. 133.—Longitudinal section through the Tongue. (From Aeby.)

its fibres upwards into the tongue on each side of the median septum, and its insertion stretches from the tip to the base. The fibres of the *glosso-palatinus* become continuous with the intrinsic transverse fibres.

The *chondro-glossus* is not always present. It is separated from the deep surface of the hyo-glossus by the lingual vessels. It is a slender muscular band which takes origin from the medial aspect of the root of the lesser cornu, and the adjoining part of the body of the hyoid bone. Its fibres ascend, to enter the tongue, where they finally spread out on the dorsum, under cover of the superior longitudinal muscle.

Musculus Longitudinalis Superior.—The superior longitudinal muscle lies immediately beneath the mucous membrane, and is a continuous layer of longitudinal fibres which covers the entire dorsum of the tongue, from the root to the tip. Towards the base of the tongue it is thinner than in front, and there it is overlapped by the transverse fibres of the hyo-

glossus, and is intermixed with the fibres of the chondro-glossus.

Musculi Longitudinales Inferiores.—The inferior longitudinal muscles are two rounded, fleshy bundles placed upon the inferior aspect of the tongue, one on each side. Posteriorly, each inferior longitudinal muscle lies in the interval between the hyo-glossus and the genio-glossus, and is attached to the hyoid bone; anteriorly, it is prolonged to the apex of the tongue between the medial border of the stylo-glossus and the genio-glossus; with the former it is more or less blended.

Musculus Transversus Linguæ.—The fibres of the transverse muscle lie under the superior longitudinal fibres, and

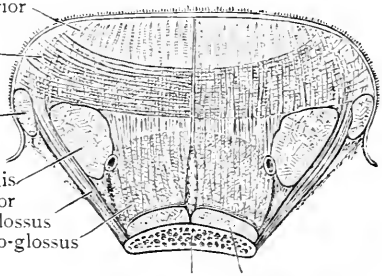

FIG. 134.—Transverse section through the Tongue. (From Aeby.)

constitute a thick layer which extends laterally, from the surface of the septum linguæ, to the side of the tongue. The fibres of the genio-glossus ascend through the transverse stratum and break it up into numerous lamellæ (Fig. 134). It is joined by the fibres of the glosso-palatinus (Henle) (Fig. 132).

Musculus Verticalis Linguæ.—The vertical fibres extend in a curved direction from the dorsum to the inferior aspect of the tongue, and decussate with the fibres of the transverse muscle.

Nerves and Vessels of the Tongue.—The nerves of the tongue are—(1) the glosso-pharyngeal; (2) the lingual; (3) the hypoglossal; and (4) a few twigs from the internal laryngeal. They should be traced on the left side of the tongue, where the mucous membrane is still in position.

The *glosso-pharyngeal nerve* has been traced up to the point

where it disappears under cover of the hyo-glossus muscle. There it divides into two branches. The *smaller* of the two extends forwards, upon the side of the tongue, and may be traced as far as a point midway between the root and the tip. The *larger* branch turns upwards, and is distributed to the mucous membrane which invests the posterior third of the dorsum linguæ. It gives twigs to the vallate papillæ, and some fine filaments may be followed to the anterior surface of the epiglottis. The glosso-pharyngeal nerve is a nerve of taste and of common sensibility.

The *lingual* and *hypoglossal nerves* are described on pages 182 and 196, and their terminal branches should now be traced as far as is possible.

The *internal laryngeal nerve* gives a few delicate filaments to the glosso-epiglottic and pharyngo-epiglottic folds and the mucous membrane of the pharyngeal aspect of the tongue.

The *arteria profunda linguæ* should be followed to the tip of the tongue, where it forms a small loop of anastomosis with its fellow of the opposite side.

Septum Linguæ.—The septum of the tongue can be seen best in a transverse section through the organ. Such a section will also display, in a measure, the transverse and vertical muscular fibres. The septum is a median fibrous partition. It is strongest posteriorly, where it is attached to the hyoid bone. It does not reach the dorsum of the tongue, being separated from it by the superior longitudinal muscle.

ENCEPHALON—THE BRAIN.

Before the dissector commences the dissections of the brain he must be familiar with its main features and with the general arrangement of its parts. For this purpose he should obtain the half of a brain which has been divided by a median sagittal section, and from which the membranes have been removed, or a cast of such a specimen, and examine it from both its medial and its lateral sides (see Figs. 135, 136).

The brain is that portion of the central nervous system which lies in the cranial cavity, where it is surrounded by three membranes, the dura mater, which has already been examined (p. 99), and the arachnoid and the pia mater, which

still cover the dissector's own specimen and which will be examined at a later stage.

The main part of the brain is formed by two somewhat hemispherical masses, called the *cerebral hemispheres*, which are so large, in the human subject, that when the brain is

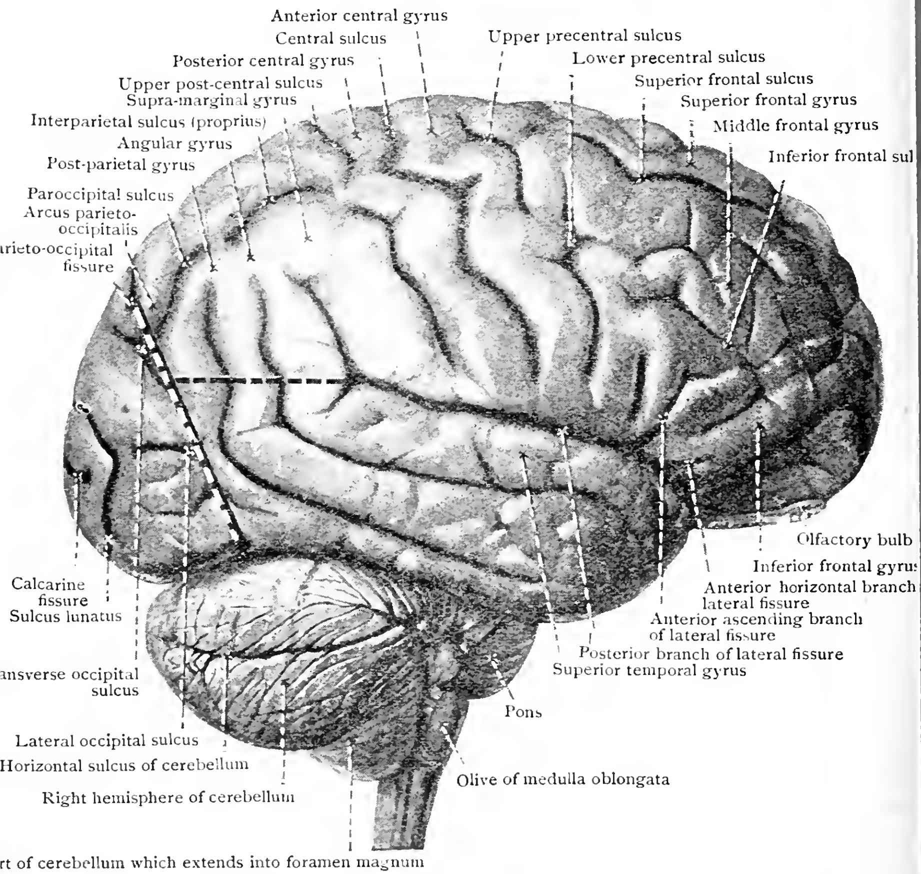

FIG. 135.—Lateral surface of Right Half of the Brain (semi-diagrammatic). The horizontal dotted line completes the separation between the parietal and temporal areas, and the oblique dotted line, which runs from the parieto-occipital fissure to the pre-occipital notch, separates the occipital from the parietal and temporal areas.

examined from above they entirely conceal all the other parts (Fig. 137).

The two hemispheres are connected together by—(1) a large transverse commissure called the corpus callosum (Fig. 136); (2) two smaller transverse commissures: (*a*) the transverse fibres of the fornix and (*b*) the anterior com-

missure; (3) by a thin membrane called the lamina terminalis, through which the fibres of the anterior commissure run (Figs. 136, 156, 159, 173).

The two hemispheres constitute, together, the *telencephalon*, which is the last formed, but the most highly developed, portion of the brain. Each hemisphere contains a cavity called the *lateral ventricle*, and there are, therefore, in the telencephalon two lateral ventricles, a right and a left, known also, though less commonly, as the first and the second (Figs. 163, 164, 165).

Immediately below and between the two cerebral hemispheres lies a portion of the brain called the *diencephalon*. It is continuous, posteriorly, with the mesencephalon or mid-brain, and, anteriorly and laterally, with the cerebral hemispheres. In the interior of the diencephalon there is a cavity called the third ventricle (Figs. 136, 168). The cavity is continuous, anteriorly, through apertures called the *interventricular foramina*, with the lateral ventricles of the telencephalon, and, posteriorly, with a canal, called the *aquæductus cerebri*, which runs through the mid-brain and connects the cavity of the diencephalon with that of the *rhombencephalon* or *hind-brain*.

When examined from its ventricular side, each half of the diencephalon is seen to be separated into two parts, a dorsal and a ventral, by an antero-posterior sulcus called the *sulcus hypothalamicus*; the dorsal part is called the *thalamus*, the ventral part is the *hypothalamus*. In Fig. 136 the point and the adjacent part of the arrow lie in the hypothalamic sulcus.

The dorsal wall of the cavity of the diencephalon is called the *roof of the third ventricle*, and from it a conical mass, called the *pineal body*, projects backwards over the mid-brain; it forms part of the *epithalamus*. The remainder of the epithalamus lies anterior and lateral to the pineal body, on the upper and posterior part of the thalamus, and it consists of the *habenula* and the *trigonum habenulæ*, on each side (Fig. 176).

Forming part of the ventral wall of the diencephalon are two round, white bodies, called the *corpora mamillaria*, and further forwards is a conical projection called the *tuber cinereum*, which is connected with the *hypophysis* by a thin stalk, called the *infundibulum* (Figs. 136, 139). All the parts of the ventral wall are parts of the hypothalamus.

Behind and somewhat below the diencephalon lies the mesencephalon or mid-brain. It is separable into—(1) a dorsal portion, the *lamina quadrigemina* or tectum, which is divided

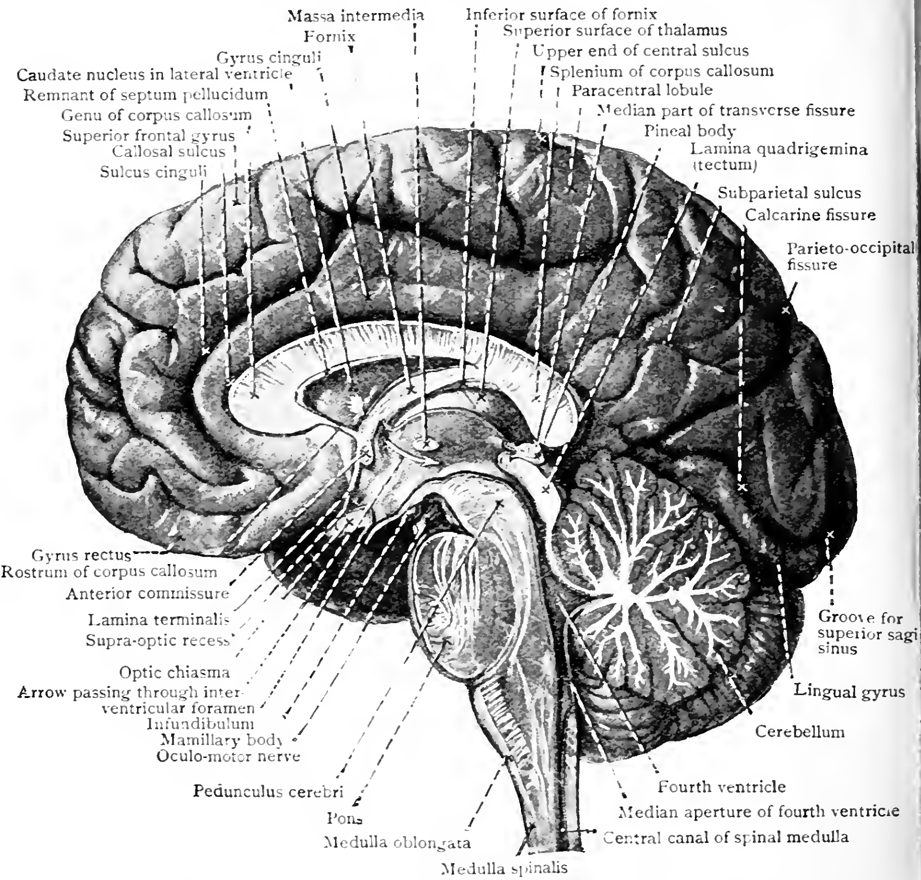

FIG. 136.—Medial surface of the Right Hemisphere, and the structures seen after a sagittal section has been made through the Corpus Callosum, the Fornix, the Diencephalon, the Mesencephalon, and the Rhombencephalon, and after the Septum Pellucidum has been removed from between the Corpus Callosum and the Fornix. The arrow passes through the interventricular foramen from the right lateral ventricle to the third ventricle, where it lies in the hypothalamic sulcus in the side wall of the third ventricle.

by a longitudinal and a transverse sulcus into four rounded bodies called the *colliculi* or *corpora quadrigemina* (Fig. 195); and (2) a ventral part, cut by a depression, the *interpeduncular fossa*, into two rounded columns, the *pedunculi cerebri*. The mid-brain is traversed, between the lamina quadrigemina and

the pedunculi, by a canal, termed the aquæductus cerebri, which connects the third ventricle, in the diencephalon, with the fourth ventricle, in the hind-brain.

Still lower and more posteriorly—that is, below and behind the mid-brain—is the *rhombencephalon* or *hind-brain*. It also is separable into dorsal and ventral portions, and between them is the cavity of the hind-brain, called the *fourth ventricle* (Fig. 136). The dorsal portion is the *cerebellum*; it lies immediately below the posterior parts of the cerebral hemispheres and above and behind the fourth ventricle. The ventral part of the hind-brain consists of an upper part, called the *pons*, which is continuous with the pedunculi of the mid-brain, and a lower part, called the *medulla oblongata*, which is continuous, below, with the spinal medulla.

When the brain was removed, the dissector noticed that the cerebral hemispheres occupied the anterior and middle fossæ of the cranium and that, more posteriorly, they lay on the tentorium cerebelli—a fold of dura mater which separated them from the hind-brain (Figs. 32, 35). The dissector noted also, after the removal of the tentorium cerebelli, that the hind-brain occupied the posterior fossa of the cranium, and that the mid-brain passed from the posterior fossa to the middle fossa through an oval notch, the incisura tentorii.

The brain is surrounded by three membranes—the dura mater, the arachnoid, and the pia mater; and between the arachnoid and the pia mater lie the main trunks of the blood vessels of the brain.

The dura mater was examined during and after the removal of the brain from the cranial cavity (pp. 99-102); but, before the arachnoid, the pia mater, and the blood vessels which lie between them, are studied, the dissector must be acquainted, not only with the main subdivisions of the brain, but he must have also a good knowledge (1) of the names of the fissures and sulci of the cerebral hemispheres, (2) of the names and positions of their various borders, surfaces, and lobes, and (3) of the position of the cerebral nerves. He should, therefore, obtain a brain from which the membranes have been detached and in which the mid-brain has been divided horizontally so that the lower part of the mid-brain and the hind-brain can be removed. He should obtain also a cerebral hemisphere which has been separated from its

fellow of the opposite side and from the mid-brain, and from which the membranes have been removed.

If actual specimens cannot be obtained good casts will serve the present purpose.

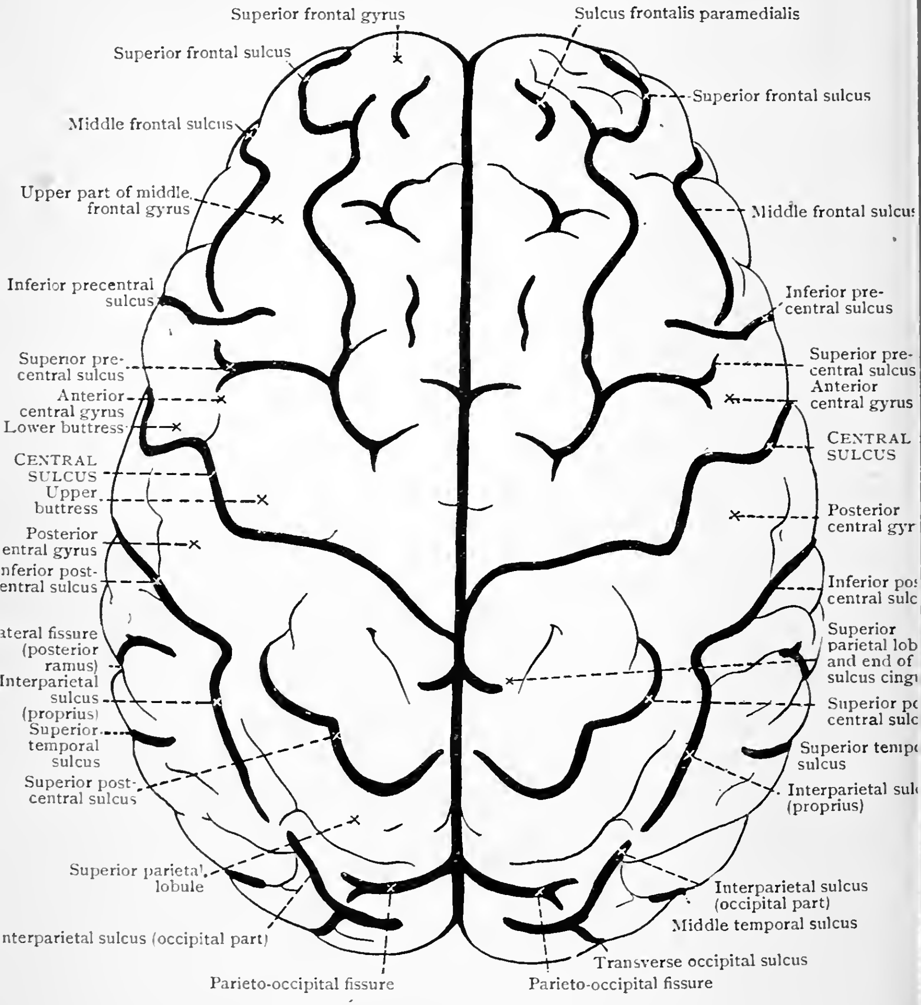

FIG. 137.—View of the Hemispheres from above (semi-diagrammatic).

Having obtained the specimens, he must examine them from above, from below, from the lateral and the medial sides; and he should commence the inspection by examining the upper aspects of the specimens. As he does that he will note the difference between the blunt and rounded

anterior end, which is called the *frontal pole*, and the more pointed posterior end, called the *occipital pole*, and he cannot fail to note that the surface of each hemisphere, at which he is looking, is convex and is directed upwards and laterally, and may therefore be termed the *supero-lateral surface*, and he will note, further, that it is moulded into numerous curved ridges of cerebral substance. The ridges are called *gyri*, and they are separated more or less completely from one another by narrow depressions, some of which are called *sulci* and others *fissures*. All the fissures and some of the sulci are named, but there are many small unnamed sulci.

A mere glance will convince the dissector that the majority of the gyri, at which he is looking, run antero-posteriorly, but that two gyri on each side, which lie a little posterior to the centre of the antero-posterior length of the hemispheres, have an entirely different direction; they run obliquely from below upwards and backwards. They form, therefore, distinct landmarks; they are known as the *anterior* and *posterior central gyri*, and the cleft which lies between them is called the *central sulcus* (Figs. 135, 137) (O.T. fissure of Rolando); in the majority of cases its upper end cuts the upper or *supero-medial border* of the hemisphere.

Between the upper end of the central sulcus and the occipital pole of the hemisphere, but nearer the latter than the former, a deep cleft cuts the supero-medial border of the hemisphere, and extends for a short distance, laterally, on the supero-lateral surface; it is the lateral part of the *parieto-occipital fissure* (Fig. 137).

The dissector should, if possible, insert the brain, or the model with which he is working, into a sagittal section of a skull of convenient size, and note that the upper end of the central sulcus corresponds with a point on the vertex of the skull which lies 12 *mm.* (*half an inch*) *behind* the centre point between the root of the nose and the external occipital protuberance, the nasion and the inion respectively, and that the parieto-occipital fissure is placed about 6 *mm. in front of* the lambda.

When the dissector has satisfied himself regarding the points mentioned, he should examine the supero-lateral surface of the hemisphere from the lateral side. Again he will note the general antero-posterior direction of the gyri and sulci, and the markedly different direction of the central

sulcus and the anterior and posterior central gyri. He will note also that, immediately below the lower end of the central sulcus, more rarely continuous with it, there is a very well-marked antero-posterior cleft; it is the posterior ramus of the *lateral fissure* (Sylvian) (Fig. 135). The lateral fissure commences on the inferior surface of the hemisphere (Fig. 138), and divides, immediately after it reaches the lateral surface, into anterior horizontal, anterior ascending, and posterior rami, all of which the dissector must identify (Figs. 135, 152). The posterior ramus is always easily identified, but the anterior rami may present difficulty.

The part of the hemisphere which lies below the lateral fissure is the anterior part of the temporal lobe; it ends anteriorly in a rounded point called the *temporal pole.*

The dissector should next turn his attention to the borders of the hemisphere as seen from the lateral side (Fig. 135). They are *supero-medial*, *infero-lateral*, and *superciliary.*

The *supero-medial border* is convex. It extends from the *frontal pole* to the *occipital pole*, along the side of the superior sagittal venous sinus, and separates the supero-lateral surface from the medial surface.

The *infero-lateral border* is concavo-convex. It extends from the occipital to the temporal pole. Its posterior and larger part lies along the line of the transverse venous sinus, and its anterior part runs along the line of the petro-squamous suture. It separates the supero-lateral surface from the posterior part of the inferior surface of the hemisphere. On this border, about a third of its length from the occipital pole, there is a distinct notch, called the *pre-occipital notch*, caused by the terminal portion of a vein which descends on the hemisphere to the transverse sinus.

The *superciliary border* extends from the temporal pole to the frontal pole. It corresponds in position, anteriorly, with the superciliary arch of the skull, and it separates the supero-lateral surface from the anterior or orbital part of the inferior surface. The dissector should verify the above statements by placing his specimen, if possible, in sagittal and horizontal sections of skulls of convenient size.

For purposes of description and localisation the greater part of each hemisphere is divided, by means of fissures and sulci, into areas called lobes, and within the area of each lobe there are, as a rule, several gyri.

Portions of four of the lobes, the *frontal*, the *parietal*, the *occipital* and the *temporal*, are visible on the supero-lateral surface.

The **frontal lobe** lies anterior to the central sulcus and above the stem and the anterior part of the posterior ramus of the lateral fissure. In it, immediately anterior to the central sulcus, is the *anterior central gyrus*, in which is the motor area of the cerebral cortex (Fig. 153). The anterior central gyrus is partially separated from the more anterior part of the frontal lobe by a *precentral sulcus*, which is generally divided into upper and lower portions. Anterior to the pre-central sulcus there are three gyri which run antero-posteriorly; they are named from above downwards, the *superior*, *middle*, and *inferior frontal gyri* (Figs. 135, 137).

The dissector should note—(1) that the anterior horizontal and anterior ascending rami of the lateral fissure cut into the inferior frontal gyrus; and (2) that, whilst the frontal lobe is partly covered by the frontal bone, a considerable part of its posterior portion, including the anterior central gyrus and the posterior parts of the antero-posterior gyri, is under cover of the anterior part of the parietal bone (Fig. 177).

The **parietal lobe** is bounded, anteriorly, by the central sulcus; posteriorly, by the parieto-occipital fissure and a line prolonged from it to a notch (Fig. 135) on the infero-lateral border called the *pre-occipital notch*; inferiorly, by the posterior ramus of the lateral fissure, and a line prolonged backwards from the point where that fissure turns from a horizontal to a vertical direction to the line from the parieto-occipital fissure to the pre-occipital notch. The supero-lateral surface of the parietal lobe is separated into three main areas. Immediately posterior to the central sulcus is the *posterior central gyrus*. It is bounded, posteriorly, by the *post-central sulcus*, and it is the region of ordinary sensation (Fig. 153). Behind the post-central sulcus the parietal lobe is separated into an *upper* and a *lower parietal lobule*, by an antero-posterior sulcus called the *sulcus interparietalis proprius*.

The **occipital lobe** lies behind the parieto-occipital fissure and the line which connects that fissure with the pre-occipital notch. Its surface is divided into four areas by three sulci. The area in the region of the occipital pole is marked off by a curved sulcus, concave backwards, called the *sulcus lunatus*. The larger anterior part is divided by two antero-posterior

sulci, called the *lateral occipital sulcus* and *paramedial occipital sulcus*, into three gyri—the superior, middle, and inferior.

The lateral surface of the **temporal lobe** is divided by two sulci, which run antero-posteriorly, into superior, middle, and inferior temporal gyri.

When the survey of the supero-lateral surface is completed, a specimen should be examined in which the lips of the lateral fissure have been separated or removed. In such a specimen it will be obvious that at the bottom of the fissure there is a sunken area of the brain cortex (Fig. 157). It is called the **insula**, and it is separated from the adjacent parts by a sulcus called the *circular sulcus.*

After the general relations of the supero-lateral surface have been noted the medial surface of the hemisphere should be examined. Upon it, nearer its anterior than its posterior end, and nearer its lower than its upper border, will be seen the surface of section of the severed *corpus callosum* (Fig. 136).

The corpus callosum consists of a *trunk*, which terminates posteriorly in a free, thick, rounded posterior end, called the *splenium*, and anteriorly in a bent anterior extremity called the *genu.* From the genu a tapering portion of the corpus callosum, termed the *rostrum*, passes downwards and backwards. It ends below in a thin lamina, called the *lamina terminalis*, which descends till it reaches the ovoid transverse section of the *optic chiasma*, which connects together the two optic nerves. The lamina terminalis passes behind the optic chiasma, and joins the tuber cinereum in the floor of the third ventricle (Figs. 136, 159). The transverse, small and round, white bundle which passes through the lamina terminalis, above the optic chiasma, is the anterior commissure.

In the median plane, in the angle between the body, genu, and rostrum of the corpus callosum, there is a thin vertical lamina called the *septum pellucidum.* It is bounded below and behind by a flat band of white matter, called the *fornix* (Figs. 136, 156).

The boundaries of the medial surface of the hemisphere are—(1) The *supero-medial border*, which extends from the frontal pole to the occipital pole, and separates the medial from the supero-lateral surface. (2) The *medial occipital border*, which extends from the occipital pole to the splenium of the corpus callosum; it separates the medial surface from the posterior part of the inferior surface. (3) The *medial*

orbital border, which runs from a point immediately in front of the optic chiasma to the frontal pole, separating the medial surface from the anterior part of the inferior surface.

Between the medial occipital and the medial orbital borders the lower boundary of the medial surface is formed by the lower margin of the splenium and the lower margin of the fornix, which lie immediately above the diencephalon.

The corpus callosum is separated from the *gyrus cinguli*, which is immediately adjacent to it, by the *callosal sulcus* (Fig. 136).

The gyrus cinguli is separated from the adjacent parts of the medial surfaces of the frontal and parietal lobes by the *sulcus cinguli*, which turns upwards at its posterior end, and cuts the supero-medial border of the hemisphere, a short distance behind the upper end of the central sulcus (Figs. 136, 156).

Some distance in front of its posterior end, the sulcus cinguli gives off a branch which ascends towards the supero-medial border. That branch is not named but it lies parallel with, or slightly in front of, the pre-central sulcus on the supero-lateral surface of the hemisphere. The portion of the medial surface of the hemisphere which lies between the posterior end of the sulcus cinguli and the unnamed upturned branch, corresponds in a general way with the upper ends of the posterior and anterior central gyri, and it is termed the *paracentral lobule* (Figs. 136, 159).

The part of the medial surface above the sulcus cinguli and between the frontal pole and the paracentral lobule is the medial part of the superior frontal gyrus; and the part which extends from the frontal pole to the optic chiasma, below the sulcus cinguli, is the *gyrus rectus*, which will be seen also on the inferior surface.

Behind the upturned, posterior end of the sulcus cinguli, but in direct line with its main portion, is a small separate sulcus, called the *subparietal sulcus*; and cutting the supero-medial border of the hemisphere about a fourth of its length from the occipital pole is the *parieto-occipital fissure*, which crosses the posterior part of the medial surface. The lower end of the parieto-occipital fissure joins an important fissure called the *calcarine* at an acute angle. That part of the medial surface which lies above the sub-parietal sulcus, and between the parieto-occipital fissure and the upturned end of

the sulcus cinguli, is termed the *præcuneus*; it is the medial part of the superior parietal lobule.

Cutting the supero-medial border a short distance above the occipital pole is the *calcarine fissure*. It is a deep fissure

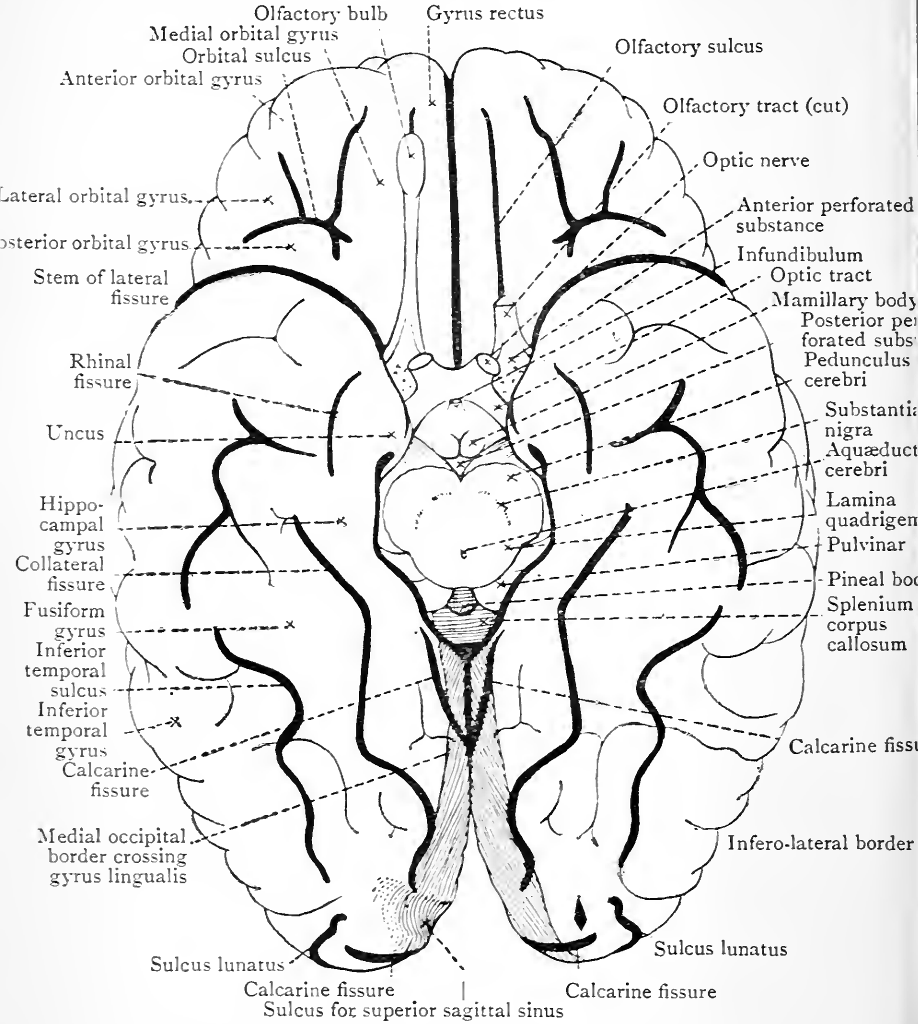

FIG. 138.—Inferior surfaces of Hemispheres (semi-diagrammatic).

which runs forwards on the medial surface. It turns downwards across the anterior part of the medial occipital border and at that point it is joined by the parieto-occipital fissure. Then it runs obliquely downwards and forwards in the posterior part of the inferior surface below the splenium of the

corpus callosum. The wedge-shaped region of the cortex of the hemisphere between the calcarine fissure and the parieto-occipital fissure is called the *cuneus*; and the portion of the medial surface of the hemisphere below the calcarine fissure is the posterior portion of the *lingual gyrus*, the remainder of which is on the inferior surface. Both the cuneus and the lingual gyrus are parts of the occipital lobe.

In the majority of cases the posterior part of the medial surface of the occipital lobe is marked by a definite vertical depression caused by the posterior part of the superior sagittal sinus (Fig. 154).

After the examination of the medial surface is completed, the dissector should examine the lower surface of a specimen from which the hind-brain and the lower part of the mid-brain have been removed (Fig. 138).

Upon each side he will note the three poles of the corresponding hemisphere—frontal, temporal, and occipital.

The part anterior to the temporal pole is the anterior part of the inferior surface, and at the same time it is the inferior surface of the frontal lobe.

It is bounded, anteriorly and laterally, by the superciliary border; medially, by the medial orbital border; and, posteriorly, in the lateral and greater part of its extent, by the stem of the lateral fissure, which separates it from the temporal lobe, but the medial part of its posterior boundary is a sulcus which intervenes between it and a small triangular area at the side of the optic chiasma, called the *anterior perforated substance*. Lying parallel with the medial orbital border is a sulcus, the *olfactory sulcus*, in which the olfactory bulb and the olfactory tract are lodged. The gyrus which lies to the medial side of the olfactory sulcus is the *gyrus rectus*, already seen on the medial surface of the hemisphere. The portion of the surface which lies lateral to the olfactory sulcus is concave, the concavity being due to the upward projection of the roof of the orbit on which it rests, and the gyri of this area are called orbital gyri. As a rule, there are four *orbital gyri*, a medial, a lateral, an anterior, and a posterior; they are separated from one another by a series of sulci, the *orbital sulci*, which have, collectively, an H-shaped outline.

The posterior part of the inferior surface, which lies behind the temporal pole, looks downwards and medially,

when the brain is in position in the cranium. It rests, in the posterior part of its extent, upon the tentorium cerebelli, and, more anteriorly, upon the anterior surface of the petrous

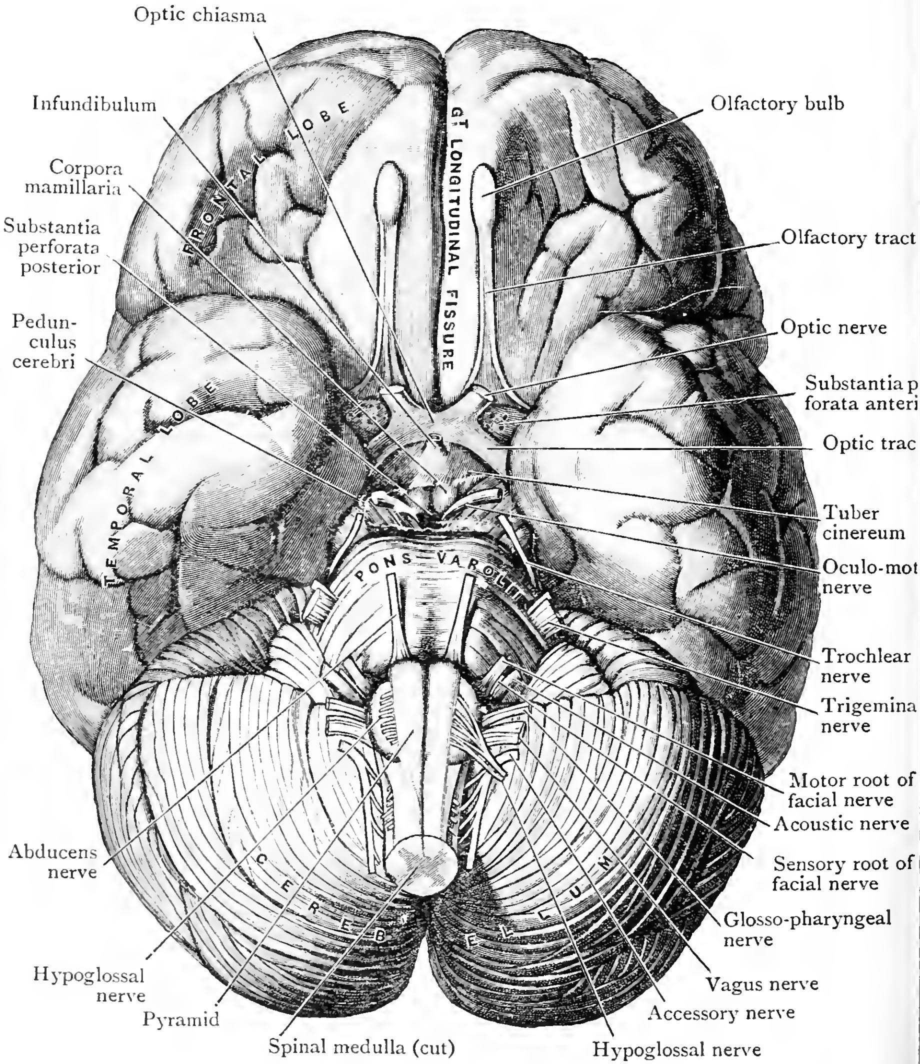

FIG. 139.—The Base of the Brain with the Cerebral Nerves attached.

portion of the temporal bone and the great wing of the sphenoid. On account of its relation to the tentorium, it is frequently called the *tentorial surface.*

The posterior part of the inferior surface is bounded

anteriorly by the temporal pole, posteriorly by the occipital pole; laterally by the infero-lateral border, which separates it from the supero-lateral surface; medially, in the posterior part of its extent, by the medial occipital border, which separates it from the medial surface, and, more anteriorly, by a fissure called the chorioidal fissure, which lies between it and the sublentiform portion of the hemisphere.

Upon the part which rests upon the petrous portion of the temporal bone, a short distance posterior to the temporal pole, will be seen a depression produced by the eminentia arcuata of the temporal bone. The part of the brain cortex which lies immediately antero-lateral to the depression rests, in the ordinary position, on the tegmen tympani and the petro-squamous suture. It lies, therefore, immediately above the epi-tympanic recess or attic of the tympanic cavity, from which it is separated merely by its membranes and a very thin plate of bone.

Crossing the medial occipital border, a short distance posterior to the corpus callosum, is the stem or anterior part of the *calcarine fissure*, already mentioned. It runs forwards for a short distance on the posterior part of the inferior surface. The part of the cortex between it and the splenium of the corpus callosum is the *isthmus*; it is continuous, above, with the gyrus cinguli, and, below, with the *hippocampal gyrus*. The hippocampal gyrus runs forwards and its anterior end turns upwards forming a hook-shaped bend, called the *uncus*. The posterior part of the hippocampal gyrus is termed the *paradentate area* (Fig. 156), and the anterior part is known as the *piriform area*. Continuous with the paradentate area, but lying posterior to it and below the stem of the calcarine fissure, is the *lingual gyrus*, which runs backwards and turns round the medial occipital border to the medial surface of the occipital lobe, where it was previously noted. Lateral and anterior to the piriform area, and on a lower plane, is a small but definite fissure, called the *rhinal fissure*, and posterior to the rhinal fissure and lateral to the paradentate area and the lingual gyrus, on a lower plane, is a definite sulcus, which runs antero-posteriorly, and is called the *collateral fissure*. The gyrus which lies below and lateral to the collateral fissure has been termed the *fusiform gyrus*; it is also called the occipito-temporal gyrus. Between it and the infero-lateral border lies the inferior temporal sulcus,

which separates it from the inferior part of the inferior temporal gyrus (Fig. 138).

When the survey of the inferior surfaces of the cerebral hemispheres is completed, the inferior aspect of a brain, or a cast, in which the mid- and hind-brain sections are still *in situ*, or in which they can be replaced, should be examined.

When that is done it will be noted that the posterior sections of the inferior surfaces of the hemispheres are concealed by the cerebellum, but the more anterior parts of the inferior surfaces are still visible. Between the anterior parts of the inferior surfaces, in the median plane, is the anterior part of the longitudinal fissure. Behind the anterior part of the longitudinal fissure lies the *optic chiasma*, but if the chiasma is carefully turned backwards, the lamina terminalis will be seen passing upwards and forwards into the longitudinal fissure (Fig. 162). At its antero-lateral angles the optic chiasma receives the optic nerves, and from each postero-lateral angle it gives off an optic tract, which runs postero-laterally and disappears from view under cover of the piriform area.

Behind the optic chiasma is the tuber cinereum with the infundibulum projecting from its apex to connect it with the hypophysis. Behind the tuber cinereum lie two round white bodies called the corpora mamillaria, and still more posteriorly is the deepest part of the *interpeduncular fossa*, which lies between the medial borders of the pedunculi cerebri. The superior boundary of the interpeduncular fossa is the *posterior perforated substance.*

The pedunculi cerebri run upwards, forwards and laterally, at the sides of the interpeduncular fossa. The upper end of each disappears into the base of the corresponding hemisphere, and its lower end is continuous with the pons of the hind-brain.

Springing from the medial side of each pedunculus is the corresponding oculo-motor nerve, and curving round its lateral side is the trochlear nerve.

Below the pedunculi cerebri of the mid-brain is the *pons* of the hind-brain, which is connected, on each side, with the corresponding hemisphere of the cerebellum.

Springing from each side of the pons, immediately medial to the corresponding hemisphere of the cerebellum, are the motor root and sensory root of the trigeminal nerve of that side.

Below the pons, in the vallecula between the hemispheres of the cerebellum, is the *medulla oblongata.* Springing from the sulcus between the medulla oblongata and the pons, are the abducens, the facial, and the acoustic nerves, in that order from the median plane to the lateral border, on each side.

The medulla oblongata is cleft, in the median plane, by an anterior longitudinal fissure which is bounded, on each side, by a longitudinal elevation called a *pyramid.* At the lateral side of the upper part of each pyramid is an oval prominence called the *olive*, and between the olive and the pyramid lie the fila of the *hypoglossal nerve*; whilst attached to the sides of the medulla oblongata, a little dorsal to the olive, are the fila of the glosso-pharyngeal, the vagus, and the accessory nerves, in that order from above downwards.

At the sides of the pons and the medulla oblongata are the inferior surfaces of the hemispheres of the cerebellum.

When the positions of the fila of origin of the cerebral nerves have been noted, the hind-brain and the lower part of the mid-brain should be removed. When that has been done the posterior sections of the inferior surfaces of the hemispheres will be exposed. They are separated from each other, posteriorly, in the median plane, by the posterior part of the longitudinal fissure, but they are united, more anteriorly, immediately dorsal to the anterior part of the mid-brain, by the splenium of the corpus callosum (Fig. 138).

When the points mentioned above have been verified the dissector should examine the dorsal aspect of the hind-brain, which is formed by the cerebellum, and he should note that it is separable into two hemispheres united by a median ridge called the *superior vermis.* The antero-posterior length of the superior vermis is not so great as the antero-posterior length of the hemispheres; therefore the hemispheres are separated, anteriorly, by an *anterior notch* and, posteriorly, by a *posterior notch.*

The dissector should terminate his inspection of the general features of the brain by gently separating the medulla oblongata from the inferior aspect of the cerebellum, if he is dealing with a specimen and not a cast; when he has done that, he will be able to convince himself that the roof of the cleft or *vallecula,* in which the medulla oblongata lies, is formed by the inferior part of the middle portion of the cerebellum,

which projects downwards into the vallecula, and is called the *inferior vermis.*

When the inspection of specimens from which the membranes have been removed is finished, the dissector should turn to the examination of the membranes which still cover his own specimen; they are the arachnoid and the pia mater.

Arachnoidea Encephali.—The arachnoid forms an intermediate covering for the brain. It is placed between the dura mater and the pia mater; it is directly continuous with the arachnoid of the spinal medulla; and it is connected with the dura mater and the pia mater along the nerve roots and along the blood vessels of the brain. It is an exceedingly thin and delicate membrane, which can be seen best on the base of the brain, because, in that locality, it is not so closely applied to the pia mater as elsewhere. Unlike the pia mater it does not (except in the case of the longitudinal and the lateral fissures) dip into the sulci or fissures on the surface of the cerebrum and cerebellum. It bridges over the inequalities on the surface of the brain and it is spread out in the form of a very distinct sheet over the medulla oblongata, the pons, and the hollow on the lower surface of the brain which lies anterior to the pons. The cut ends of several of the cerebral nerves will be seen passing through the arachnoid; whilst, anteriorly, immediately to the lateral side of the optic nerve, the internal carotid artery will be noticed piercing it.

Cavum Subarachnoideale.—The interval between the arachnoid and the pia mater receives the name of the subarachnoid space. It contains the subarachnoid fluid, and is broken up by a meshwork of fine filaments and trabeculæ, which connect the two bounding membranes (viz., the arachnoid and the pia mater), in the most intimate manner, and which form a delicate sponge-like interlacement between them. Where the arachnoid passes over the summit of a cerebral gyrus, and is consequently closely applied to the subjacent pia mater, the meshwork is so close and the trabeculæ so short that the two membranes cannot be separated from each other. To the dissector they appear to form a single lamina. In the intervals between the rounded margins of adjacent gyri distinct angular spaces exist between the arachnoid and the pia mater. In those spaces the subarachnoid tissue can be studied, and it will be seen that the spaces serve as communicating

channels for the free passage of the subarachnoid fluid from one part of the brain to another. The larger branches of the arteries and veins of the brain traverse the subarachnoid space; their walls are directly connected with the subarachnoid trabeculæ and are bathed by the subarachnoid fluid.

Cisternæ Subarachnoideales.—In certain situations the arachnoid is separated from the pia mater by intervals of considerable depth and extent. Such expansions of the subarachnoid space are termed subarachnoid cisterns. In them the subarachnoid tissue is relatively reduced. There

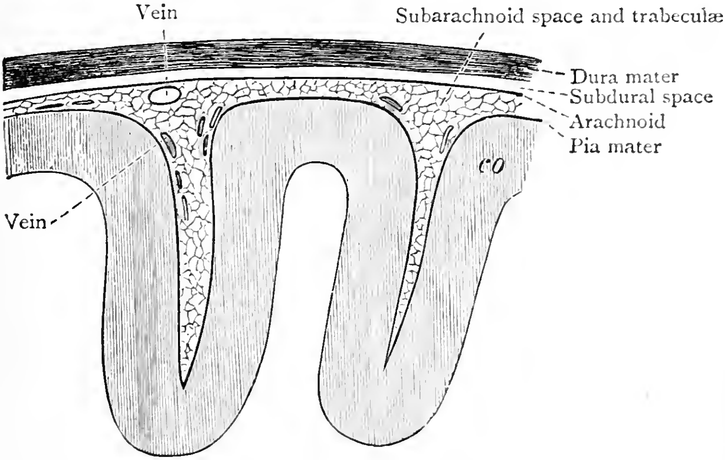

FIG. 140.—Diagrammatic section through the Meninges of the Brain. (Schwalbe.)

co. Grey matter of cerebral gyri.

is no longer a close meshwork; the trabeculæ connecting the two bounding membranes take the form of long filamentous intersecting threads which traverse the spaces. The dissector will obtain a beautiful demonstration of the conditions described by dividing the sheet of arachnoid which is spread over the medulla oblongata and pons, and turning the two pieces gently aside. The division must be made in the median plane with scissors.

Certain of the cisternæ require special mention. The largest and most conspicuous is called the *cisterna cerebello-medullaris* (O.T. *magna*) (Fig. 141). It is a direct upward continuation of the posterior part of the subarachnoid space of the spinal meninges into the posterior part of the cranium. It is formed by the arachnoid membrane bridging over the

wide interval between the medulla oblongata and the posterior part of the inferior surface of the cerebellum.

The *cisterna pontis* is the name given to another of the subarachnoideal spaces. It is the continuation upwards, on the floor of the cranium, of the anterior part of the sub-

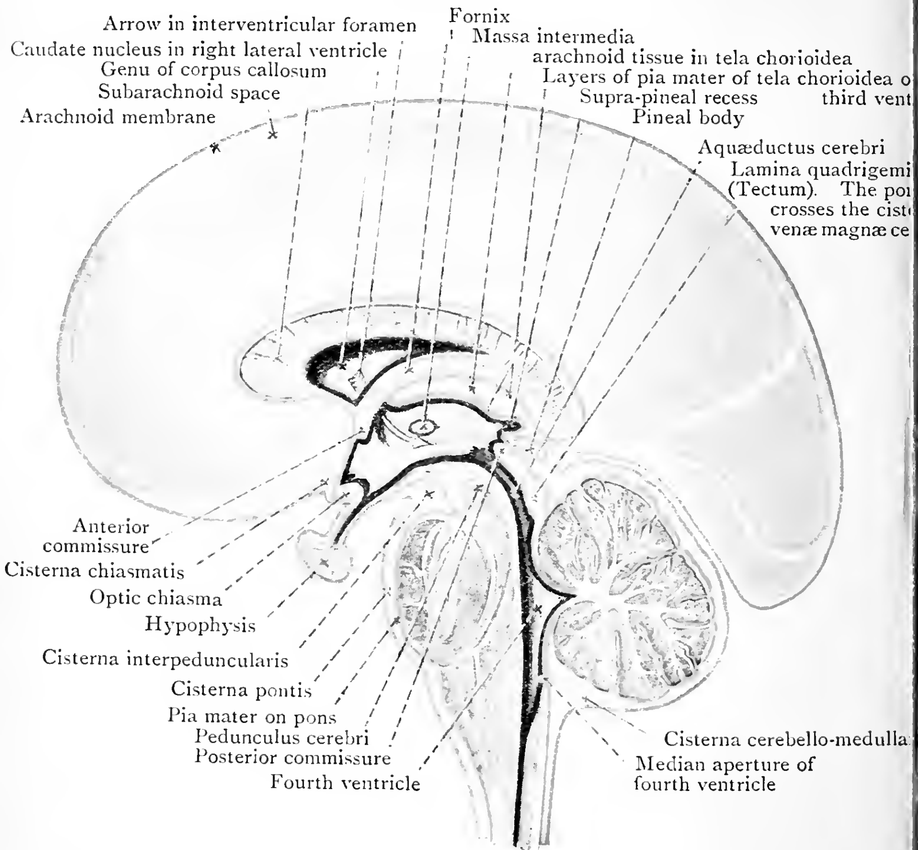

FIG. 141.—Diagram showing some of the Subarachnoid Cisternæ. Dark blue line indicates arachnoid membrane. Pale blue, subarachnoid tissue containing cerebro-spinal fluid. Dark red indicates cut margin of pia mater. Pale red, surface of pia mater from which arachnoid has been removed. Purple indicates epithelial lining of the cavities of the brain.

arachnoid space of the spinal meninges. In the region of the medulla oblongata it is continuous, on each side, with the cerebello-medullary cistern, so that that subdivision of the brain is completely surrounded by a wide subarachnoid space. Within the cisterna pontis are the vertebral and basilar arteries.

Anterior to the pons the arachnoid membrane crosses between the projecting temporal lobes, and covers in the deep hollow in that region of the base of the brain. The space so enclosed is called the *cisterna interpeduncularis*, and within it are placed the large arteries which take part in the formation of circulus arteriosus. The cisterna interpeduncularis is continuous, anteriorly, with the *cisterna chiasmatis*, which lies anterior to the optic chiasma and lodges the anterior cerebral arteries (Fig. 141).

All the subarachnoid cisterns communicate in the freest manner with one another, and also with the narrow subarachnoid intervals on the surface of the cerebrum. The subarachnoid space does not communicate in any way with the subdural space. In certain localities, however, it communicates with the ventricular system of the brain by small apertures. Three such apertures are described in connection with the fourth ventricle, whilst another slit, on each side, is said to lead from the cisterna interpeduncularis into the lower and anterior end of the corresponding inferior horn of the lateral ventricle.

Extending laterally from the cisterna interpeduncularis, on each side, is the *cisterna fossæ lateralis cerebri*, which runs along the stem of the lateral fissure into the lateral fossa, which is the recess in which the insula lies. In it lie the middle cerebral vessels. Anteriorly, the cisterna chiasmatis is continuous with a prolongation which extends into the longitudinal fissure along the anterior cerebral vessels. A dilatation of the subarachnoid space over the dorsum of the mid-brain, around the great cerebral vein (O.T. vena magna Galeni), is called the *cisterna venæ magnæ cerebri*.

The cisterna venæ magnæ cerebri was opened when the mid-brain was divided, during the removal of the brain. The dissector should now examine the other cisternæ by carefully dividing the arachnoid, where that has not already been done.

Dissection.—Divide the arachnoid, in the median plane, along the anterior surfaces of the medulla oblongata and the pons (if the division has not been made previously), and turn the flaps to the sides. When that has been done the upper ends of the vertebral arteries, and the basilar artery, which is formed by their union, will be exposed, lying in the cisterna pontis.

Carry an incision backwards and laterally, through each flap of arachnoid, into the angle between the medulla oblongata and

the posterior part of the inferior surface of the cerebellum, and so open the large cisterna cerebello-medullaris. It lies between the inferior vermis of the cerebellum and the dorsal surface of the medulla oblongata, and it communicates, through the thin dorsal wall of the medulla oblongata, with the cavity of the hind-brain, which is called fourth ventricle. Note that a large branch of each vertebral artery, called the posterior inferior cerebellar, passes into the cerebello-medullary cistern, on its way to its distribution to the posterior part of the inferior aspect of the cerebellum.

Turn again to the lower surface of the pons, and carry the median incision in the arachnoid, forwards, into the inter-peduncular region, as far as the posterior border of the in-fundibulum, and so open the cisterna interpeduncularis. Note that the arachnoid which forms the floor or inferior wall of the interpeduncular cistern is perforated posteriorly, on each side, by the oculo-motor nerve, and anteriorly and more laterally by the internal carotid artery.

Take away the arachnoid which forms the lower wall of the cisterna interpeduncularis, and so expose the basilar artery as it terminates in its two posterior cerebral branches. Find also the two posterior communicating arteries, which run forwards, one on each side, from the corresponding posterior cerebral artery, to join the internal carotid arteries, which enter the antero-lateral angles of the cisterna interpeduncularis.

Draw the optic chiasma carefully backwards and cut through the arachnoid immediately in front of it, to open the cisterna chiasmatis. Carry the incision in the arachnoid of the cisterna chiasmatis laterally, round the lateral borders of the optic chiasma, and note that the cisterna chiasmatis communicates, round the margins of the chiasma, with the cisterna inter-peduncularis. Take away the arachnoid which has already been divided, and note that beyond the lateral borders of the optic chiasma, both the cisterna interpeduncularis and the cisterna chiasmatis are prolonged laterally, on each side, between the frontal and the temporal regions of the brain, into the stem of the lateral fissure.

Clean the internal carotid arteries as they lie at the sides of the optic chiasma, and note—(1) that each communicates with the corresponding posterior cerebral artery by means of the posterior communicating artery; (2) the division of each internal carotid into a middle and an anterior cerebral branch. The middle cerebral branch runs laterally into the stem of the lateral fissure, and the anterior cerebral turns medially above the optic chiasma, in the cisterna chiasmatis, to reach the longi-tudinal fissure, into which it passes; but as it enters the fissure it is connected with its fellow of the opposite side by the anterior communicating artery.

It is not advisable to follow the cerebral arteries further at this stage.

Granulationes Arachnoideales (O.T. **Pacchionian Bodies**). —The connection of the arachnoideal granulations with the arachnoid has been referred to already (p. 100).

Pia Mater Encephali.—The pia mater forms the immediate investment of the brain. It is finer and more delicate than the corresponding membrane of the spinal medulla, and it follows closely all the inequalities on the surface of the brain. Thus, in the case of the cerebrum, it forms a fold within every sulcus and lines both sides of the cleft. On the cerebellum the relation is not so intimate; it is only the larger fissures of the cerebellum which contain folds of pia mater.

It has been noted that the larger blood vessels of the brain run in the subarachnoid space; the finer twigs enter the

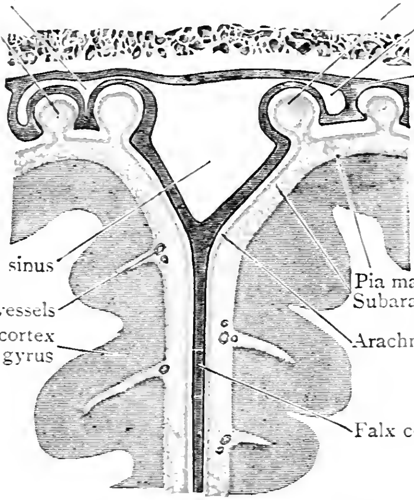

FIG. 142.—Diagram of a frontal section through the middle portion of the cranial vault and subjacent brain to show the membranes of the brain and the arachnoideal granulations.

pia mater, where they ramify and anastomose before passing into the substance of the brain. As they enter the brain they carry with them sheaths derived from the pia mater. Consequently, if the dissector raises a portion of that membrane from the surface of the cerebrum, a number of fine processes will be seen to be withdrawn from the cerebral substance. They are the blood vessels, and they give the deep surface of the membrane a rough and flocculent appearance.

The pia mater is not confined to the exterior of the brain. A fold is carried into its interior. This will be exposed in the dissection of the brain, and will be described under the name of the tela chorioidea (O.T. velum interpositum) of the third ventricle (Fig. 174).

BLOOD VESSELS OF THE BRAIN.

The dissector should commence his study of the blood vessels of the brain by an inspection of the veins of the brain. He will readily find and easily follow some of the venous blood channels, but he will have considerable difficulty in tracing others from their commencements to their terminations. Indeed, it may be that he will have to refer to specially prepared specimens for confirmation of some of the points about to be noted.

The Veins of the Brain.—The venous channels of the brain include the venous blood sinuses of the dura mater, and the veins which open into them. The venous sinuses were noted when the dura mater was studied after the removal of the brain (pp. 113, 114, 115).

Veins of the Cerebral Hemispheres.—The veins which join the venous sinuses of the dura mater, and their tributaries are still *in situ*. The majority of them lie in the subarachnoid space on the surfaces of the hemisphere, but a few issue from the interior of the brain. One of the latter, the *great cerebral vein*, was seen when the upper parts of the brain were removed from the cranium (p. 108). It emerges from beneath the splenium of the corpus callosum, and runs upwards and backwards, in the cistern of the great cerebral vein, to terminate by joining the anterior end of the straight sinus in the tentorium cerebelli (p. 107, Fig. 35). The cut end of it can still be seen lying in the cistern, immediately posterior to the splenium of the corpus callosum.

Entering the great cerebral vein on each side is a tributary called the basal vein; it runs round the side of the pedunculus cerebri, from the region of the anterior perforated substance. The basal vein is formed, in the subarachnoid space below the anterior perforated substance, by the union of three veins, viz., (1) the anterior cerebral vein with (2) a vein from the surface of the insula, called the *deep middle cerebral vein*, and (3) the *anterior striate vein*, which issues from the substance of the brain. The *anterior cerebral vein* drains the greater part of the medial surface of the hemisphere of the same side and issues from the anterior part of the longitudinal fissure, immediately anterior to the optic chiasma; then it

crosses the anterior perforated substance, on its way to its termination in the basal vein.

The dissector may find it difficult or even impossible to demonstrate the basal vein and its tributaries if the veins are empty, but in a certain number of specimens they are found without difficulty.

The veins of the supero-lateral surface of the hemisphere are divided into two groups—the superior and the inferior cerebral veins.

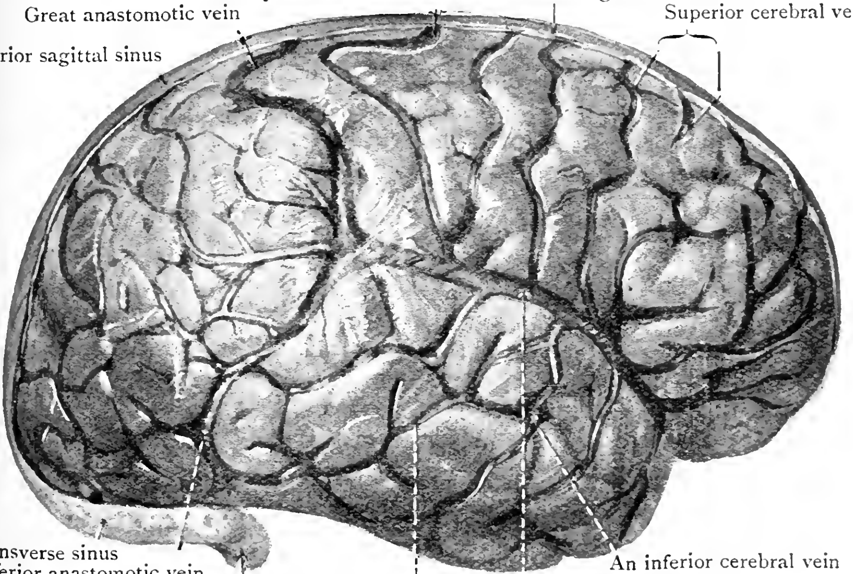

FIG. 143.—Veins of the supero-lateral surface of the Hemisphere. The dura mater has been removed, but the arachnoid and pia mater are *in situ*.

The *superior cerebral veins* run upwards towards the supero-medial border of the hemisphere where they terminate in the superior sagittal sinus. They vary in number from six to twelve. The more anterior veins enter the sinus at right angles, but the orifices of the more posterior veins are directed obliquely forwards—that is, against the blood stream in the sinus (Fig. 143).

The majority of the *inferior cerebral veins* converge towards the posterior ramus of the lateral fissure, where they terminate in the *superficial middle cerebral vein*, which runs forwards, along the fissure, and then, leaving the posterior branch of

the fissure, it turns medially, along the stem of the fissure, and ends in the cavernous sinus. If the vein is traced, its terminal cut end will be found in the region of the anterior part of the interpeduncular fossa.

The inferior cerebral veins which do not terminate in the superficial middle cerebral vein run downwards, towards the infero-lateral border of the hemisphere, and they end in the transverse sinus.

In almost all cases there is a direct communication between the superior sagittal sinus and the posterior part of the superficial middle cerebral vein, by means of a vein which is called the *great* or *superior anastomotic vein*; and, very frequently, the posterior part of the superficial middle cerebral vein communicates with the transverse sinus, through one of the inferior cerebral veins which opens into both, and which is called the *inferior* or *small anastomotic vein.* Both the communications may become of importance in cases in which the posterior part of the superior sagittal sinus or the commencements of both transverse sinuses are obstructed.

The majority of the veins on the medial surface of the hemisphere terminate in the anterior cerebral vein, which runs along the upper surface of the corpus callosum, but some end in the inferior sagittal sinus, and some ascend to the superior sagittal sinus.

The veins from the anterior part of the inferior surface of the hemisphere join either the superficial middle cerebral vein or the anterior cerebral vein; those from the posterior part of the inferior surface pass to the basal vein, to the superior petrosal sinus, to the straight sinus, and to the transverse sinus. The veins from the interior of the hemispheres which join the great cerebral vein will be described later (see p. 444).

Veins of the Mid-Brain.—There are no large veins from the mid-brain, and the small veins which return the blood from that part of the brain end either in the great cerebral vein, or in the basal veins, or in both.

Veins of the Cerebellum.—The veins on the superior surface of the cerebellum pass forwards; some terminate in the great cerebral vein, others in the superior petrosal sinuses. Some of the veins of the inferior aspect of the cerebellum end in the straight sinus, others in the transverse sinus, the occipital sinus, or an inferior petrosal sinus.

Veins of the Pons.—The veins from the upper part of the pons join the basal vein, and those from the inferior part either join the cerebellar veins or they end in the inferior petrosal sinuses.

Veins of the Medulla Oblongata.—The smaller veins of the medulla oblongata converge to an anterior and a posterior median vein, or they run along the roots of the last four pairs of cerebral nerves. The anterior median vein communicates, above, with the veins of the pons, and, below, with the veins of the spinal medulla. The posterior median vein also communicates, below, with the veins of the spinal medulla, and it terminates, above, either in the inferior petrosal sinuses or in the basilar plexus. The efferents which accompany the last four cerebral nerves end either in the inferior petrosal sinuses, in the upper parts of the internal jugular veins, or in the pharyngeal plexus.

Arteries which supply Blood to the Brain.—Four main arterial trunks carry blood into the cranium for the supply of the brain—viz., the two internal carotid arteries and the two vertebral arteries. The vertebral arteries enter through the foramen magnum, whilst the internal carotid arteries gain admittance through the lacerate foramina, after traversing the carotid canals. Both the vertebral and the internal carotid arteries were divided when the brain was removed from the cranium. The cut ends of the internal carotids will be seen, at the base of the brain, close to the sides of the optic chiasma. When the remains of the membranes are taken away from around it, each internal carotid will be found to divide, a short distance above its cut extremity and immediately below the anterior perforated substance, into a larger branch, the middle cerebral artery, which runs laterally, and a smaller branch, the anterior cerebral artery, which runs medially.

The vertebral arteries curve round the sides of the medulla oblongata and they unite at its upper border, in the median plane, to form the basilar artery, which runs to the upper border of the pons, where it divides into the two posterior cerebral arteries.

But the cerebral arteries which spring from the internal carotid arteries of opposite sides are brought into association with one another, and with the posterior cerebral arteries, which spring from the basilar, by a remarkable and complete

series of anastomoses which take place at the base of the brain, as well as by the anastomoses of their terminal branches in the pia mater on the surfaces of the hemispheres.

The more striking series of anastomoses are those at the base of the brain; they constitute the circulus arteriosus (Willis), and the arteries which take part in the formation of the circle lie in the cisterna interpeduncularis and the cisterna chiasmatis.

Circulus Arteriosus (O.T. **Circle of Willis**).—The series of anastomoses which forms the arterial circle lies at the

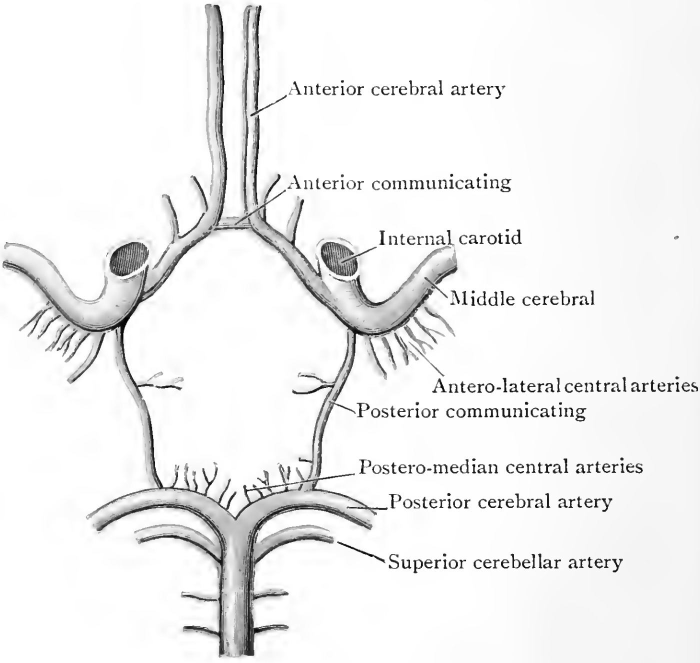

FIG. 144.—Diagram of the Circulus Arteriosus.

base of the brain, in the deep hollow anterior to the pons and around the optic chiasma. The so-called circle has, in reality, a heptagonal or hexagonal outline, and the vessels which compose it lie, as already stated, in the cisterna interpeduncularis and the cisterna chiasmatis. Anteriorly it is formed by the anterior communicating artery, which links together the two anterior cerebral arteries. On each side is the posterior communicating artery, connecting the internal carotid (from which the anterior cerebral springs) with the posterior cerebral. The arterial ring is completed posteriorly

by the bifurcation of the basilar artery into the two posterior cerebral vessels (Fig. 144). As a rule, the circulus arteriosus is not symmetrical. One posterior communicating artery is almost invariably larger than its fellow of the opposite side.

Two systems of branches, both going to the cerebrum but differing greatly in their mode of distribution, proceed from the cerebral arteries. One system consists of very numerous,

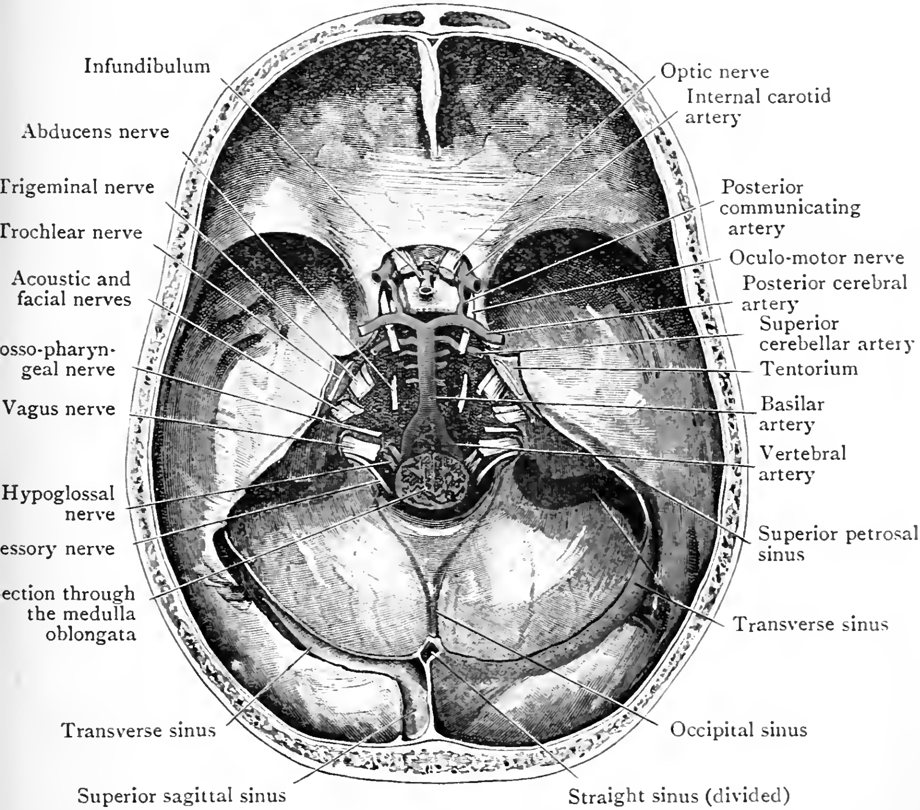

FIG. 145.—Floor of the Cranium after the removal of the Brain and the Tentorium Cerebelli. The blood vessels forming the Circulus Arteriosus have been left in place.

slender twigs, which, as a rule, come off in groups in certain localities, and at once pierce the substance of the cerebrum to gain its interior. It is the system of *central* or *basal branches.* The other system is composed of branches which ramify over the surface of the cerebrum, and it is termed the system of *cortical branches.* The central parts of the brain, including the basal ganglia, receive their blood supply from

the central system, and the vessels which constitute that group do not anastomose with each other. The cortical vessels supply the cerebral cortex and the finer branches, which ramify in the pia mater, anastomose with one another; therefore, the neighbouring vascular districts of the cerebral cortex are not sharply cut off from one another.

Arteriæ Vertebrales.—Each vertebral artery enters the sub-arachnoid space, in the upper part of the vertebral canal, by piercing the dura mater and the arachnoid. Gaining the interior of the cranium, through the foramen magnum, it runs upwards, at first, on the side of the medulla oblongata, but it soon inclines to the anterior aspect of the medulla oblongata, and, meeting its fellow of the opposite side in the median plane, it unites with it, at the lower border of the pons, to form the basilar artery.

The branches given off from the intracranial part of the vertebral artery are:—

1. Posterior spinal.
2. Posterior inferior cerebellar.
3. Anterior spinal.
4. Bulbar.

Arteria Spinalis Posterior.—The posterior spinal artery is the first branch given off from the vertebral artery after it pierces the dura mater. It passes, downwards, on the spinal medulla along the line of the posterior nerve-roots (p. 90).

Arteria Cerebelli Inferior Posterior.—The posterior inferior cerebellar artery is the largest branch of the vertebral artery. It takes origin immediately above the posterior spinal artery, and pursues a tortuous course backwards, on the side of the upper part of the medulla oblongata, between fila of the hypoglossal nerve, and then between fila of the vagus. Finally, turning round the restiform body, it gains the vallecula of the cerebellum and enters the cisterna cerebello-medullaris, where it ends by dividing into two terminal branches. One of the branches ramifies on the posterior part of the inferior surface of the corresponding cerebellar hemisphere, the other runs backwards, in the vallecula, in the groove between the vermis and the hemisphere supplying both. The trunk of the artery gives branches to the medulla oblongata which supply the olive, and the fibres of the spino-cerebellar, the spino-thalamic, the rubro-spinal, and the olivo-cerebellar tracts, as well as the nuclei of the vagus and glosso-pharyngeal nerves (Bury and Stopford).

Arteria Spinalis Anterior.—The anterior spinal artery arises

near the lower border of the pons, and it is rare to find the vessels of the two sides of equal size. They converge, on the anterior surface of the medulla oblongata, and unite to form the commencement of the median vessel which extends downwards on the ventral face of the spinal medulla.

The *bulbar arteries* are minute vessels which enter the substance of the medulla oblongata ; they spring both from the vertebral artery itself and also from its branches.

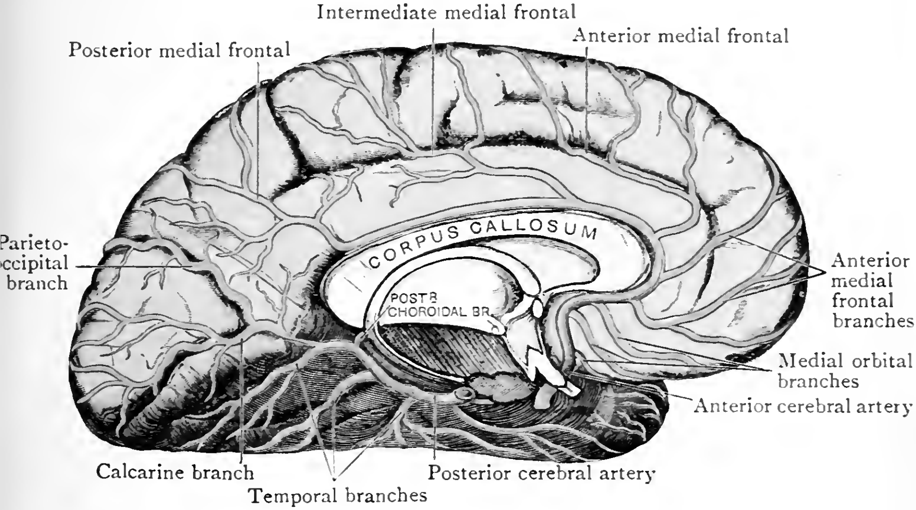

FIG. 146.—Medial and Tentorial Surfaces of the left Cerebral Hemisphere. The district supplied by the anterior cerebral artery is tinted *purple* ; by the middle cerebral artery, *blue* ; and by the posterior cerebral artery, *red*. (Semi-diagrammatic.)

Arteria Basilaris.—The basilar artery runs from the lower border to the upper border of the pons, occupying the median groove of the pons and lying in the median part of the cisterna pontis. It is formed, at the lower border of the pons, by the union of the two vertebral arteries, and it divides, at the upper border, into the two posterior cerebral arteries. It is supported anteriorly by the basilar portion of the occipital bone and the dorsum sellæ of the sphenoid (Fig. 38).

The majority of the branches which spring from the basilar artery arise from its sides and pass laterally from it. They are :—

1. Pontine.
2. Internal auditory.
3. Anterior inferior cerebellar.
4. Superior cerebellar.
5. Posterior cerebral.

Rami ad Pontem.—The pontine branches are numerous slender twigs which run, laterally, on the surface of the pons before they enter its substance.

Arteria Auditiva Interna.—The internal auditory artery will be seen amongst the pontine branches. It accompanies the acoustic nerve into the internal acoustic meatus, and is distributed to the internal ear.

Arteria Cerebelli Inferior Anterior.—The anterior inferior cerebellar artery inclines postero-laterally to reach the anterior part of the inferior surface of the cerebellum.

Arteria Cerebelli Superior.—The superior cerebellar artery, on each side, is a large vessel which springs from the basilar close to its termination. It winds laterally and backwards, round the corresponding pedunculus cerebri, along the upper border of the pons, to the upper surface of the cerebellum, where its terminal branches ramify before entering the grey matter.

Arteria Cerebri Posterior.—Immediately beyond the origin of the two superior cerebellar arteries the basilar artery bifurcates into the two posterior cerebral arteries, which diverge from each other and curve laterally and backwards round the mesencephalon. Then they run backwards towards the inferior surface of the splenium of the corpus callosum. In the first part of its course each posterior cerebral artery lies deeply, in the interval between the corresponding pedunculus cerebri and the hippocampal gyrus; then it enters the calcarine fissure, and ends, in the fissure, by dividing into two terminal branches, viz., the calcarine and the parieto-occipital (Figs. 146, 147).

The oculo-motor nerve passes forwards in the interval between the posterior cerebral and the superior cerebellar arteries, close to the place where they arise from the basilar; and the small trochlear nerve winds round the pedunculus cerebri below the posterior cerebral artery.

The following branches spring from each posterior cerebral artery:—

Central or basal	Postero-median. Postero-lateral. Posterior chorioidal.	Cortical	Temporal. Calcarine. Parieto-occipital.

The *postero-median central arteries* arise close to the origin of the parent trunk. They proceed upwards, in the interval between the pedunculi cerebri, and, after piercing the substantia perforata posterior (O.T. posterior per-

forated spot), they supply the hypothalamus, the thalamus, and the medial part of the pedunculus cerebri.

The *postero-lateral central arteries* are small slender twigs which arise on the lateral surface of the pedunculus cerebri, and go to the lamina quadrigemina and the thalamus.

The *posterior chorioidal artery* goes to the tela chorioidea of the third ventricle and the chorioid plexus of the lateral ventricle (Figs. 148 and 163).

The cortical branches are distributed to the medial, inferior, and supero-lateral surfaces of the posterior part of the hemisphere (Figs. 146, 147, 148).

The *temporal branches*, two or three in number, turn laterally, over the hippocampal gyrus, and ramify on the inferior surface of the temporal lobe of the cerebrum (Figs. 146 and 147).

The *calcarine branch* follows the calcarine fissure to the occipital pole of the cerebral hemisphere, round which it turns to reach the lateral surface of the occipital lobe. It is the chief artery of supply to the cuneus and the lingual gyrus, and is therefore specially concerned in the nutrition of the visual centres of the cerebral cortex (Fig. 146).

The *parieto-occipital artery* is the smaller of the two terminal branches of the posterior cerebral. It runs upwards in the parieto-occipital fissure, and at the supero-medial margin of the hemisphere it curves laterally to reach the supero-lateral surface of the occipital lobe. It supplies branches to the cuneus and præcuneus (Figs. 146, 148).

Arteria Carotis Interna.—The cut extremity of the internal carotid artery will be found at the lateral side of the optic chiasma, in the angle between the optic nerve and the optic tract. Thence the artery turns laterally, below the substantia perforata anterior, close to the commencement of the lateral fissure, and it ends by dividing into the anterior and middle cerebral arteries (Fig. 144). The *middle cerebral artery* is the larger of the two terminal branches. It appears to be the continuation of the parent trunk and it runs laterally into the stem of the lateral fissure. The *anterior cerebral artery*, on the other hand, passes medially from the internal carotid, almost at a right angle. Consequently emboli pass more frequently into the middle cerebral than into the anterior cerebral artery. From each internal carotid artery, after it has emerged from the cavernous sinus (p. 239), the following branches arise:—

1. Ophthalmic (already studied, p. 252).
2. Posterior communicating.
3. Chorioidal.
4. Middle cerebral.
5. Anterior cerebral.

Arteria Communicans Posterior.—The posterior communicating artery, as a rule, is a slender branch which passes

backwards to join the posterior cerebral, between its postero-median and postero-lateral groups of central twigs (Fig. 144).

Arteria Chorioidea.— The chorioidal artery enters the inferior cornu of the lateral ventricle, and passes into the chorioid plexus in that cavity (Fig. 147).

Arteriæ Cerebri Anteriores.—Each anterior cerebral artery runs first horizontally, above the optic chiasma, towards the median plane (Figs. 146, 147). Then, bending sharply upon

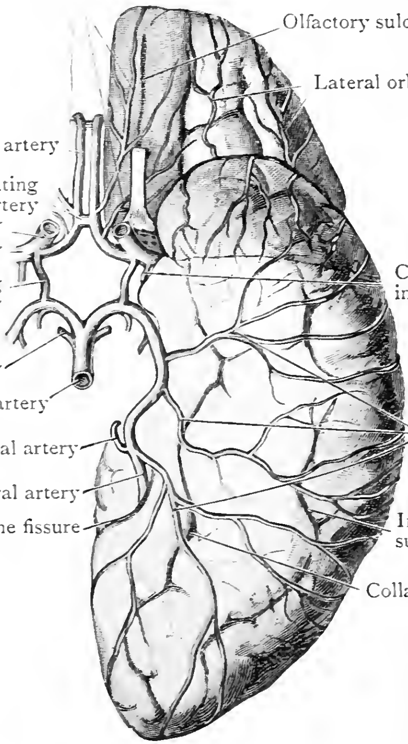

FIG. 147.—Inferior surface of the Cerebral Hemisphere. The districts supplied by the three cerebral arteries are tinted differently: posterior cerebral artery, *red*; middle cerebral artery, *blue*; anterior cerebral artery, *purple*.

itself, it turns upwards, in the anterior part of the longitudinal fissure, anterior to the lamina terminalis, and along the rostrum to the genu of the corpus callosum, round which it bends; then it passes backwards, along the medial face of the corresponding hemisphere, on the upper surface of the corpus callosum, to the parieto-occipital fissure (Fig. 146). As it lies anterior to the lamina terminalis it is connected with the opposite anterior cerebral artery by the *anterior communicating*

artery, and as it passes along the longitudinal fissure, between the hemispheres, it lies close to its fellow of the opposite side.

Numerous branches proceed from each anterior cerebral artery :—

Basal or central	Antero-medial.
Cortical .	Medial orbital. Anterior medial frontal. Intermediate medial frontal. Posterior medial frontal.

The *antero-medial arteries* pierce the base of the brain anterior to the optic chiasma. They supply the rostrum of the corpus callosum, the lamina terminalis, and the septum pellucidum.

The cortical branches supply the greater part of the medial surface of the hemisphere and parts of the orbital and supero-lateral surfaces (Figs. 146, 147, 148).

The *medial orbital branches* are two or three in number. They turn round the margin of the longitudinal fissure to reach the medial part of the orbital surface of the frontal lobe. They supply the gyrus rectus, the olfactory tract and bulb, and the medial orbital gyrus (Figs. 146 and 147).

The *anterior medial frontal artery* ramifies upon the anterior part of the medial surface of the frontal lobe, and its terminal twigs turn round the upper margin of the cerebral hemisphere, and supply the upper part of the supero-lateral surface of the frontal lobe (Fig. 146).

The *intermediate medial frontal artery* ramifies on the medial surface of the frontal lobe posterior to the preceding branch. Its terminal part passes over the paracentral lobule, and reaches the adjacent portion of the supero-lateral surface of the cerebral hemisphere (Figs. 146, 148).

The *posterior medial frontal artery* ramifies on the medial surface of the præcuneus, and its terminal twigs turn round the upper margin of the cerebral hemisphere to gain the supero-lateral surface.

Arteriæ Cerebri Mediæ.—At first each middle cerebral artery passes laterally, along the stem of the lateral fissure, and then upwards in the lateral fossa, where, on the surface of the insula, it breaks up into a number of large terminal branches. Before the posterior ramus of the lateral fissure is opened up to expose the insula in the lateral fossa, the terminal branches may be seen emerging from between its two lips (Fig. 148). Then they diverge and supply a wide area of cortex on the supero-lateral surface of the hemisphere.

The branches which spring from each middle cerebral artery may be classified as follows :—

Central or basal branches.	Antero-lateral.	
Cortical branches.	Frontal	Lateral orbital. Inferior lateral frontal. Ascending frontal.
	Parietal	Ascending parietal.
	Parieto-temporal.	
	Temporal.	

The arteries of the *antero-lateral central group* are very numerous. They pierce the substantia perforata anterior and supply the lentiform nucleus, the internal capsule and the external capsule, the caudate nucleus, and a portion of the thalamus.

The cortical branches supply the greater part of the supero-lateral surface of the hemisphere, the lateral half of the orbital surface, the lower surface of the interior part of the temporal lobe and the temporal pole (Figs. 147, 148).

The *frontal* and *parietal branches* turn round the upper lip of the posterior ramus of the lateral fissure and ascend on the supero-lateral surface of the hemisphere. The *frontal branches* are: (1) *lateral orbital*,

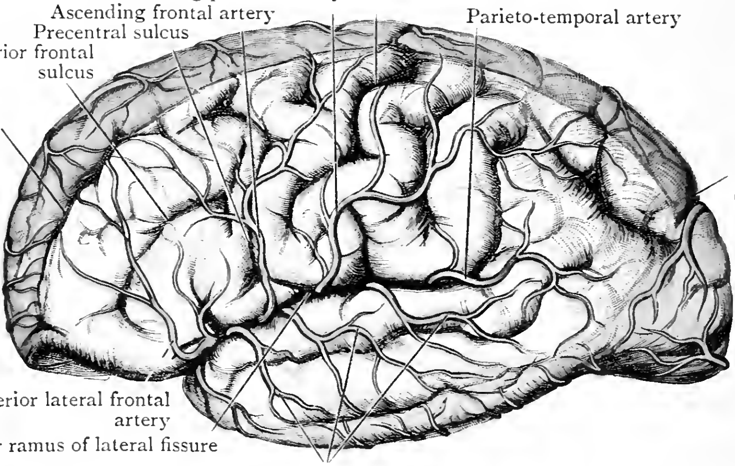

FIG. 148.—Supero-lateral surface of the Cerebral Hemisphere. The districts supplied by the three cerebral arteries are tinted differently: anterior cerebral, *purple*; middle cerebral, *blue*; posterior cerebral, *red*. (Semi-diagrammatic.)

to the lateral part of the orbital surface of the frontal lobe; (2) *inferior lateral frontal*, to the inferior and middle frontal gyri; (3) *ascending frontal*, which runs upwards in relation to the anterior central gyrus (Figs. 147, 148).

The *ascending parietal branch* extends, in an upward and backward direction, in relation to the posterior central gyrus, and its terminal twigs supply the greater part of the cortex of the superior parietal lobule (Fig. 187).

The *parieto-temporal branch* is a very large artery which issues from the posterior part of the posterior ramus of the lateral fissure; it sends branches upwards to the inferior parietal lobule, and others which incline downwards over the posterior part of the temporal lobe. Its twigs, as a rule, do not encroach upon the supero-lateral surface of the occipital lobe (Fig. 148).

The *temporal branches*, two or three in number, issue from the posterior ramus of the lateral fissure, and, turning downwards and backwards, over its lower lip (*i.e.* the superior temporal gyrus), they ramify upon the lateral surface of the temporal lobe (Fig. 148).

The dissector should note that the branches of the middle cerebral artery supply the greater part of the motor area of the cortex, the greater part of the area for ordinary sensation, and area for hearing (cp. Figs. 148 and 153).

Dissection.—When the distribution of the branches of the cerebral arteries has been noted, the dissectors must remove the blood vessels and the remains of the arachnoid first from the base of the brain and then from the supero-lateral surfaces of the hemispheres, commencing with the base. The dissection must be done with forceps and a pair of scissors. In the basal region very delicate manipulation is necessary, because the cerebral nerves, at their points of attachment to the brain, are so intimately connected with the pia mater that any undue traction applied to the membranes will tear the nerves away. Indeed, in the case of the medulla oblongata, the dissector is advised to leave the pia mater in position until the nerve-roots have been studied. The relation of the pia mater to the fourth ventricle also renders this desirable.

The removal of the arachnoid and pia mater from the supero-lateral surface must be commenced at the margins of that surface, and the membranes must be reflected towards the lateral fissure. When the margins of the fissure are reached they must be pulled apart, then the larger branches and the associated parts of the membranes, which lie in the fissure, can be seen, but they must not be removed at present. Cut through the membranes and the vessels along the margins of the fissure, but leave their deeper parts *in situ*. Of course, at the present stage, the membranes cannot be removed from every part of the brain; but as the dissection proceeds, opportunities for completing the process will arise.

After the vessels and the membranes are removed from the base and from the supero-lateral surfaces of the hemispheres, the dissectors should commence their more detailed study of the brain by the investigation of the base.

THE BASE OF THE BRAIN.

When the membranes and the blood vessels are removed from the base of the brain two large rope-like strands, called the *pedunculi cerebri* (O.T. crura), will be seen issuing from the upper part of the pons. As the peduncles emerge from the pons they are close together, but they diverge as they pass upwards and forwards, and, finally, each peduncle disappears into the base of the corresponding cerebral hemisphere. As each peduncle passes into the corresponding hemisphere it is embraced, on its lateral side, by the hippocampal gyrus, but between the gyrus and the peduncle is a white, flattened band, called *the optic tract*, which is closely

applied to the side of the peduncle. The two optic tracts converge as they pass forwards, and, finally, they are joined together by a short, transverse commissural portion termed *the optic chiasma.* The optic chiasma lies at the anterior end of the *interpeduncular fossa*, and below the posterior end of that portion of the longitudinal fissure which intervenes between the inferior surfaces of the frontal lobes of the brain. The optic nerves enter the antero-lateral angles of the chiasma.

Fossa Interpeduncularis.—The interpeduncular fossa is the rhomboidal region which is bounded posteriorly by the pons, postero-laterally by the cerebral peduncles, antero-laterally by the optic tracts, and anteriorly by the optic chiasma; within the limits of the fossa the following parts are situated—(1) the oculo-motor nerves; (2) the substantia perforata posterior; (3) the corpora mamillaria; and (4) the tuber cinereum, with the infundibulum.

Nervus Oculomotorius.—Each oculo-motor nerve issues from the medial side of the corresponding cerebral peduncle, below the posterior perforated substance (Fig. 149).

Substantia Perforata Posterior (O.T. **Posterior Perforated Space**).—The posterior perforated substance forms the roof or superior wall of the posterior and deepest part of the interpeduncular fossa. It is a layer of grey matter in which there are numerous small apertures. The apertures are caused by the postero-medial central branches of the posterior cerebral arteries, which were withdrawn from the apertures when the pia mater was removed.

Corpora Mamillaria.—The mamillary bodies are two small, white, pea-shaped eminences, placed side by side immediately anterior to the posterior perforated substance. They form part of the hypothalamic region, and, at a later stage of the dissection, their connections with the columns of the fornix will be displayed.

Tuber Cinereum.—The tuber cinereum is a slightly raised field of grey matter which occupies the interval between the optic chiasma, anteriorly, the corpora mamillaria, posteriorly, and the optic tracts laterally. Springing from the anterior part of the tuber cinereum, immediately posterior to the optic chiasma, is the infundibulum or stalk of the hypophysis. When the brain was removed the connection of the infundibulum with the hypophysis was severed (p. 106).

Substantiæ Perforatæ Anteriores.—The anterior perfor-

ated areas are small triangular districts of grey matter, one on each side. Each is bounded, posteriorly, by the uncinate extremity of the hippocampal gyrus; anteriorly, by the diverging striæ of the olfactory tract; and, medially, by the optic tract. Laterally, it passes into the roof of the lateral fissure, and is perforated by the antero-lateral central arteries (Figs. 147, 149). The grey matter of each anterior perforated area is continuous, above, with a mass of grey matter in the base of the corresponding cerebral hemisphere which is called the corpus striatum (Fig. 185).

Lamina Terminalis.—The lamina terminalis, which was originally the anterior wall of the brain, will be displayed if the optic chiasma is pulled gently backwards. It is a thin lamina which passes upwards from the chiasma into the longitudinal fissure, to become connected with the rostrum of the corpus callosum. It closes the third ventricle anteriorly, and is continuous, on each side, with the grey matter of the substantia perforata anterior (Fig. 186).

Superficial Attachments of the Cerebral Nerves.—Twelve cerebral nerves arise from or enter the brain, on each side of the median plane. They are the olfactory or first, consisting of about twenty separate filaments; the optic or second; the oculo-motor or third; the trochlear or fourth; the trigeminal or fifth; the abducent or sixth; the facial or seventh; the acoustic or eighth; the glosso-pharyngeal or ninth; the vagus or tenth; the accessory or eleventh; and the hypoglossal or twelfth.

A thirteenth pair of cerebral nerves, called the *nervi terminales*, is known. Each nervus terminalis is attached to the cerebrum posterior to the olfactory striæ. Its fibres run alongside the corresponding olfactory tract, and are distributed with the olfactory nerves to the upper parts of the wall of the nasal cavity. The functions of the nervi terminales are unknown.

Each nerve is said to have a "superficial attachment" and a "deep" origin or termination. By the term "superficial attachment" is meant the region where its fibres enter or leave the brain surface; the terms "deep termination and origin" indicate the connections which are established by the fibres of the different nerves with nuclei or clusters of nerve-cells within the substance of the brain. The nuclei are of two kinds: (1) those in connection with which the afferent or entering nerve fibres end; and (2) those from which the efferent or emerging nerve fibres arise. It is the superficial

attachments only which come under notice of the dissector at the present time.

No fewer than eight pairs of the cerebral nerves, from the fifth to the twelfth inclusive, have a superficial attachment to

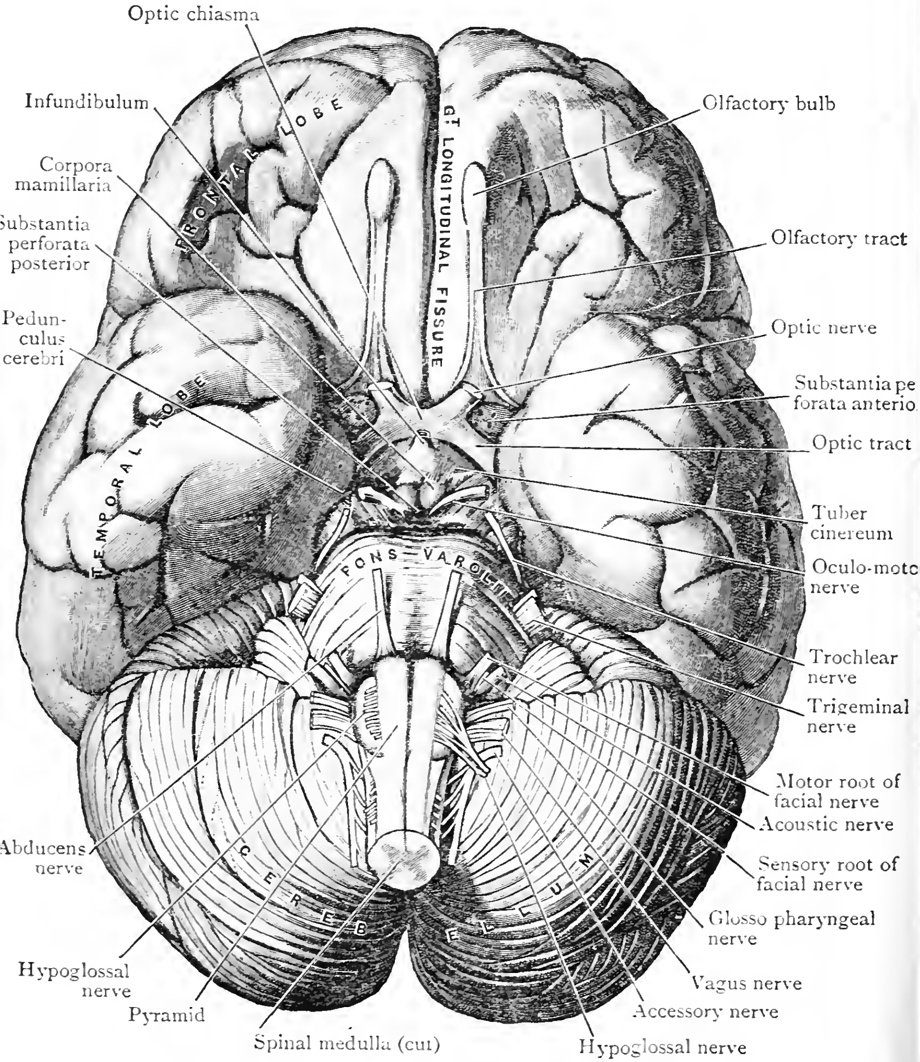

FIG. 149.—The Base of the Brain with the Cerebral Nerves attached.

the medulla oblongata and the pons—that is to the ventral part of the hind brain.

Nervus Hypoglossus.—Upon the lateral aspect of the upper half of the medulla oblongata there is a very conspicuous oval

prominence called the olive. Medial to the olive is a large elongated strand of the medulla oblongata, termed the pyramid; it is separated from the olive by a groove or sulcus which is prolonged downwards for some distance beyond the olive. From the part of the sulcus between the olive and the pyramid spring the fila of the *hypoglossal nerve* (Figs. 149, 150); and from the lower part of the sulcus some of the fila of the *anterior root of the first cervical nerve* issue.

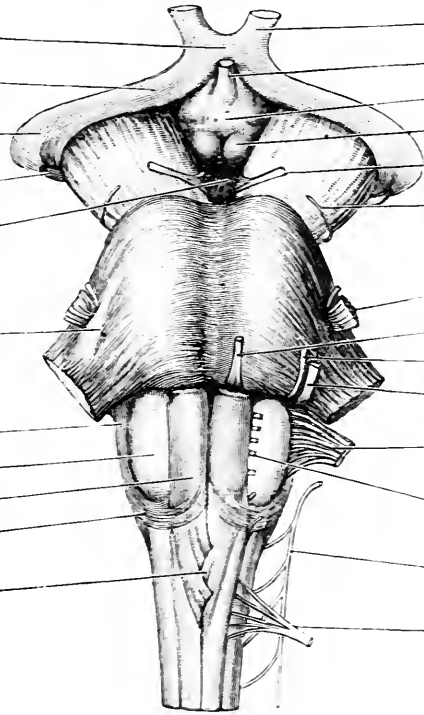

FIG. 150.—Anterior aspect of the Medulla Oblongata, Pons, and Mesencephalon of a full-time Fœtus.

Nervi Glossopharyngeus et Vagus et Accessorius.—Posterior to the olive is the post-olivary sulcus, and a little more dorsally lies the postero-lateral sulcus of the medulla oblongata, in which a continuous row of nerve fila is attached. The fila in question extend downwards, beyond the level of the olive, and are attached to the whole length of the medulla oblongata in linear order. They belong to three nerves, but it is impossible at present (seeing that the nerve-trunks which they build up are divided) to determine precisely the number of

fila which belong to each. From below upwards, the nerves which they form are the *accessory*, the *vagus*, and the *glosso-pharyngeal.* The fila of the vagus and the glosso-pharyngeal are much more closely crowded together than those of the accessory (Fig. 150).

The roots of the accessory which spring from the medulla oblongata constitute only one part of the nerve. The *spinal part* springs from the spinal medulla, as low down as the sixth

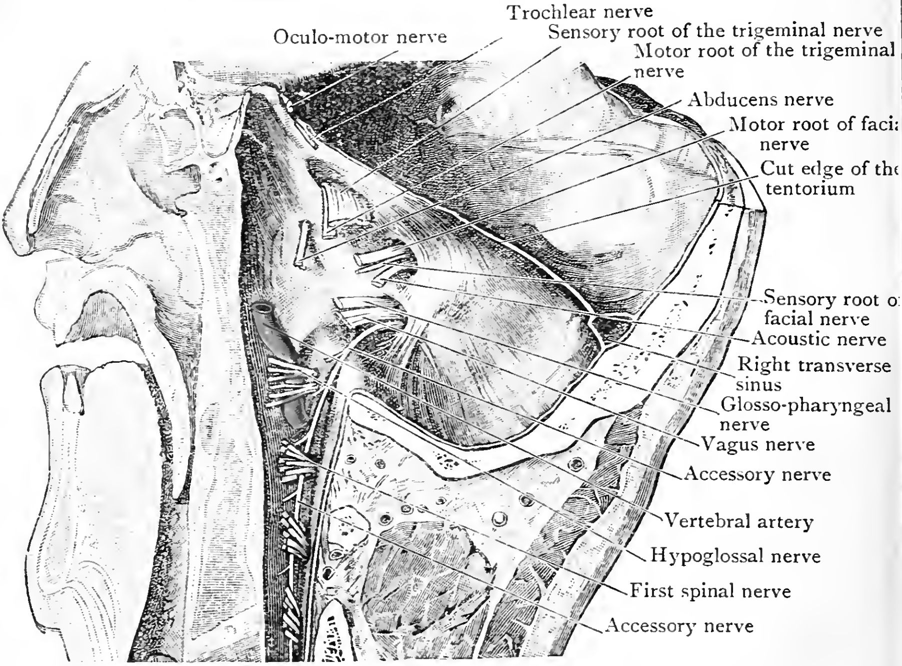

FIG. 151.—Section through the Head a little to the right of the Median Plane. It shows the posterior cranial fossa and the upper part of the vertebral canal after the removal of brain and the spinal medulla.

cervical nerve, by a series of roots which issue from the lateral funiculus, posterior to the attachment of the ligamentum denticulatum (p. 83) (Figs. 149, 151).

Nervus Acusticus et Nervus Facialis.—The acoustic and facial nerves are attached, close together, at the lower border of the pons, and immediately above the restiform body, which extends from the medulla oblongata to the cerebellum (p. 479) (Figs. 150, 151). The *acoustic nerve* is the larger of the two, and it lies on the lateral side of the facial. Its two roots embrace the restiform body; the dorsal of

the two is the cochlear root, the ventral is the vestibular root.

The *facial nerve* is attached at the lower border of the pons, just to the medial side of the acoustic nerve, by two roots —a large motor root, and a small sensory root (O.T. pars intermedia) (Figs. 150, 151). The two roots unite in the internal acoustic meatus.

Nervus Abducens.—The abducens is a small nerve which emerges from the groove between the lower border of the pons and the lateral part of the pyramid. It is flattened out near its origin and a surface view of it in that region gives a deceptive idea of its size (Figs. 149, 150).

Nervus Trigeminus.—The trigeminal is the largest of all the cerebral nerves. It is attached to the side of the pons, nearer its upper than its lower border, by two roots—a large sensory root and a small motor root, which are in a line with the facial and acoustic nerves. The large, sensory root (*portio major*) is composed of a great number of fila loosely held together, but the small, motor root (*portio minor*) is more compact, and it emerges antero-medial to the point at which the sensory root enters the pons (Figs. 149, 151).

Nervus Trochlearis.—The superficial origin of the trochlear or fourth nerve can be seen when the anterior part of the superior vermis of the cerebellum is displaced backwards. It emerges from the anterior medullary velum, on the dorsal aspect of the brain-stem, immediately below the quadrigeminal lamina. It is a slender nerve and it has a long intracranial course. In the first part of its course it winds round the lateral side of the pedunculus cerebri, between the cerebrum and cerebellum, to reach the interpeduncular region (Figs. 149, 150).

Nervus Oculomotorius.—The oculo-motor nerve issues, by several fila, from the sulcus oculomotorius on the medial face of the cerebral peduncle in the interpeduncular fossa (Figs. 149, 150).

Nervus Opticus.—The optic nerve is a large round nerve which joins the antero-lateral angle of the optic chiasma (Fig. 149).

Nervi Olfactorii.—The olfactory nerves, about twenty in number on each side, arise in the nasal mucous membrane. They pass into the cranium through the cribriform lamina of the ethmoid, and they terminate in the olfactory bulb. It is

not probable that the dissector will find any trace of them on the brain.

THE CEREBRUM.

The term cerebrum includes (1) the two cerebral hemispheres which, together, form the telencephalon and (2) the boundaries of the third ventricle which, collectively, form the diencephalon. The two parts, that is the telencephalon and the diencephalon, are intimately connected with one another.

Each hemisphere is separated from its fellow of the opposite side by a deep fissure called the longitudinal fissure. Anteriorly and posteriorly the longitudinal fissure completely separates the two hemispheres, but in the intermediate region the hemispheres are connected with one another, across the bottom of the longitudinal fissure by a large transverse commissure called the corpus callosum, which can be seen when the hemispheres are drawn apart.

Cerebral Hemispheres.—It has been pointed out already that each cerebral hemisphere possesses three surfaces, three poles and five borders. The surfaces are supero-lateral, medial and inferior. The poles are frontal, occipital and temporal. The borders are supero-medial, infero-lateral, superciliary, medial orbital and medial occipital.

The *frontal pole* is the most projecting part of the anterior extremity of the hemisphere. It is blunt and rounded, and it lies behind the medial part of the superciliary eminence of the frontal bone. The *occipital pole* is the posterior extremity of the hemisphere. It is more pointed than the frontal pole. It lies immediately above and lateral to the external occipital protuberance (inion). In a well-hardened brain the occipital pole of the right hemisphere is usually marked, on its medial aspect, by a broad groove caused by the posterior end of the superior sagittal sinus.

The *supero-lateral surface* is convex and is adapted to the concavity of the cranial vault. The *medial surface* is flat and, when the brain is *in situ*, it is more or less completely separated from the corresponding surface of the opposite hemisphere by the falx cerebri and the prolongations of the arachnoid and the pia-mater which occupy the longitudinal fissure between the two hemispheres. The *inferior surface* is irregular and is adapted to the floors of the anterior and

middle cranial fossæ, and to the upper surface of the tentorium cerebelli. It is separated into anterior and posterior parts by a deep transverse fissure called the stem of the lateral fissure. The anterior or orbital part lies on the floor of the anterior fossa, that is on the roof of the orbit. It is concave, and it looks downwards and laterally; consequently it is partially visible when the hemisphere is viewed from the lateral side (see Figs. 152, 155). The posterior part is concavo-convex. It looks downwards and medially. Its anterior extremity forms the rounded temporal pole, which abuts against the posterior part of the lateral wall of the orbit. Behind the temporal pole its anterior convex part lies on the anterior part of the floor of the middle cranial fossa which separates it from the infra-temporal fossa. The anterior part of its concave portion rests upon the anterior surface of the petrous part of the temporal bone which separates it from the tympanic cavity, the internal ear and the carotid canal. It is separated from the anterior surface of the apex of the petrous part of the temporal bone by the semilunar ganglion of the trigeminal nerve, and it is marked near its lateral margin by a depression caused by the eminentia arcuata of the temporal bone.

The posterior and longer part of the concave area rests upon the tentorium cerebelli which intervenes between it and the cerebellum.

The *supero-medial border* extends from the frontal to the occipital pole; it is convex and is in relation with the wall of the superior sagittal sinus.

The *infero-lateral border* is concave in the posterior part of its extent, where it rests upon the tentorium cerebelli and is in relation with the wall of the transverse sinus; and the anterior part, which lies along the line of union of the squamous with the petrous part of the temporal bone, is convex.

The *superciliary border* extends from the frontal to the temporal pole. It lies parallel with and above the supra-orbital margin. It separates the supero-lateral surface from the orbital part of the inferior surface.

The *medial orbital margin* can be seen at the base of the brain; it extends from the frontal pole to the optic chiasma, along the side of the inferior part of the anterior portion of the longitudinal fissure. It lies above the roof of the nose.

It separates the orbital part of the inferior surface from the medial surface.

The *medial occipital border* can be seen from below, after the hind-brain and the mid-brain have been cut away from the cerebrum, or from behind, when the posterior parts of the hemispheres are separated from one another. It extends from the occipital pole to the posterior end of the corpus callosum. It lies along the margin of the inferior part of the posterior portion of the longitudinal fissure, in relation with the wall of the straight sinus; and it separates the medial surface from the posterior part of the inferior surface.

Fissura Longitudinalis.—The longitudinal fissure is the great median cleft between the two cerebral hemispheres; anteriorly and posteriorly, it completely separates the hemispheres from each other, but the intermediate part is bounded below by the corpus callosum which passes between the hemispheres and connects them together. If the two sides of the longitudinal fissure are gently drawn asunder, the upper surface of the corpus callosum will be displayed. When the brain is *in situ* the longitudinal fissure contains the falx cerebri of the dura mater (p. 104), a fold of arachnoid, the pia mater covering the medial surfaces of the hemispheres, the anterior cerebral arteries and veins, with their branches and tributaries. The falx cerebri was removed when the brain was taken from the skull; the other membranes and the vessels are still *in situ*, and they should not be disturbed till the medial surfaces of the hemispheres can be examined (p. 419).

Dissection.—Separate the cerebellum, pons and medulla from the cerebrum, if that has not already been done, by cutting transversely through the upper part of the mid-brain. Then, if two brains are available, split one of them in the median plane by placing a long knife in the longitudinal fissure and dividing carefully the various parts which connect the two halves together. All three surfaces of each hemisphere will then be exposed, the gyri and sulci can be studied fully and satisfactorily, and the terminal parts of the anterior and posterior cerebral arteries (pp. 384, 386) can be examined. If only one brain is at the disposal of the dissectors they should not, at this stage, separate the cerebral hemispheres from each other, but should endeavour to follow out the gyri and sulci with the various parts of the brain in position. No doubt they will study the hemispheres in that way at some disadvantage, but as the dissection proceeds, opportunities will occur which will enable them to examine those districts of the surface which they can see only imperfectly at present.

Cerebral Gyri and Sulci.—The surface pattern which is presented by the cerebral gyri and sulci is, in its general features, the same in all human brains; but when the comparison is pushed into more detail many differences become manifest, not only in the brains of different subjects but also in the two cerebral hemispheres of one subject.

The depressions which intervene between the cerebral gyri vary in depth. Some are due to folding of the whole thickness of the wall of the cerebrum, and consequently they correspond with elevations of the walls of the cavities of the cerebrum which are called the lateral ventricles. Such depressions are called *complete fissures*. In this category are included—(1) the anterior portion of the calcarine fissure; (2) a portion of the collateral fissure; and (3) the chorioidal fissure. The *incomplete fissures and the sulci* are merely furrows of varying depth which do not produce any effect on the surface of the ventricular walls.

General Structure of the Cerebral Hemispheres.—Each cerebral hemisphere is composed of an outside coating of grey matter, spread in a continuous and uninterrupted layer over its surface, and an internal core of white matter. The grey coating is termed the *cerebral cortex*, whilst the white internal part is called the *medullary centre*. Each gyrus shows a corresponding structure. It has an external covering of grey matter supported upon a core of white medullary matter. But, in addition to the grey matter on the outside, there are certain large deposits of grey matter embedded in the substance of each hemisphere in its basal part. Those deposits constitute the basal ganglia, and although to a certain extent they are isolated from the grey matter on the surface, nevertheless, at certain points, they are directly continuous with it (Fig. 186).

By means of the gyri and sulci the grey matter on the surface of the hemisphere is increased, and its close association with the vascular pia mater is maintained without any unnecessary increase of the bulk of the organ. The vascular pia mater dips into every fissure and sulcus, and opportunity is, therefore, afforded for the cortical vessels to break up into twigs of exceeding fineness before they enter the substance of the hemisphere. The distribution of the blood to the grey cortex is in that way rendered uniform.

Cerebral Lobes and Interlobar Fissures and Sulci.—For purposes of localisation and description, it is customary to

divide the hemispheres into districts termed *lobes*, and, for that purpose, certain fissures and sulci are chosen which are termed *interlobar fissures and sulci*: they are the following:—

1. The lateral fissure (O.T. Sylvian).
2. The central sulcus (O.T. fissure of Rolando).
3. The parieto-occipital sulcus.
4. The collateral fissure.
5. The circular sulcus (O.T. limiting sulcus of Reil).

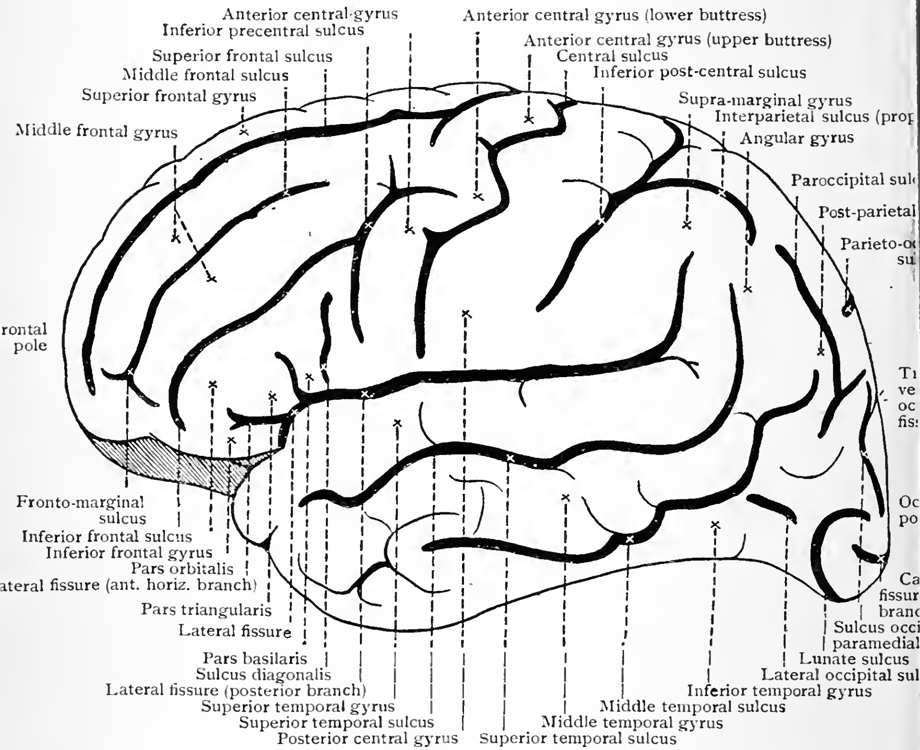

FIG. 152—Supero-lateral aspect of Left Hemisphere (semi-diagrammatic). The orbital surface is shaded.

The lobes which are mapped out by the fissures mentioned are—(1) the frontal; (2) the parietal; (3) the occipital; (4) the temporal; (5) the insula. To them may be added a sixth lobe, in no way related to the interlobar fissures, viz., the olfactory lobe.

Fissura Lateralis (O.T. **Sylvian**).—The lateral fissure is the most conspicuous fissure on the surface of each cerebral hemisphere. It is composed of a short main stem, from the lateral extremity of which three branches radiate. The *stem* is placed on the inferior surface of the cerebrum (Fig. 138).

It begins at the substantia perforata anterior. Thence it passes laterally, forming a deep cleft between the temporal pole and the orbital area of the inferior surface of the hemisphere. When it reaches the lateral surface of the hemisphere, the fissure immediately divides into three radiating branches—(1) the ramus posterior; (2) the ramus anterior horizontalis; and (3) the ramus anterior ascendens.

The *posterior branch* (Figs. 138, 152) is the longest and the most important of the three. It extends backwards, with a slight upward inclination, for a distance of 7.5 cm. (*three inches*) or more, between the temporal lobe, which is placed below it, and the frontal and parietal lobes, which lie above it. Finally, it turns upwards, into the parietal lobe, in the form of an *ascending terminal piece* (Figs. 138, 152).

The *anterior horizontal branch* (Fig. 152) runs forwards in the frontal lobe, for a distance of about 19 mm. (*three-quarters of an inch*), immediately above and parallel to the posterior part of the superciliary margin of the hemisphere.

The *anterior ascending branch* (Figs. 138, 152) passes upwards, with a slight anterior inclination, into the lower part of the lateral surface of the frontal lobe for a distance of about 25 mm. (*one inch*). In many cases the two anterior limbs spring from a common stem of variable length.

Sulcus Circularis (O.T. **Limiting Sulcus of Reil**).—If the lips of the posterior ramus of the lateral fissure are gently pulled asunder, the *insula* (O.T. island of Reil) will be seen at the bottom of the cleft which is termed the lateral fossa (Fig. 157). It is surrounded by a sulcus, called the circular sulcus, which is separable into three parts, viz., an *upper part*, bounding the insula above, a *lower part*, marking it off below, and an *anterior part* limiting it anteriorly. The insula thus mapped out is somewhat triangular in outline, and over its surface ramify branches of the middle cerebral artery.

Opercula Insulæ.—The present is a good time to study the manner in which the insula is shut off from the surface of the hemisphere. When the lateral fissure is held widely open, it will be noted that the insula is overlaid by portions of cerebral cortex which appear as if they were undermined. The overlying portions are called the *opercula insula*, and it is their opposed margins which form the boundaries of the lateral fissure. The opercula are four in number, and are

named—(1) temporal, (2) fronto-parietal, (3) frontal, and (4) orbital. They are easily distinguished.

The *temporal operculum* extends upwards over the insula from the temporal lobe; it forms the lower lip of the posterior ramus of the lateral fissure (Fig. 152).

The *fronto-parietal operculum* is carried downwards over the insula to meet the temporal operculum. Its margin forms the upper lip of the posterior ramus of the lateral fissure.

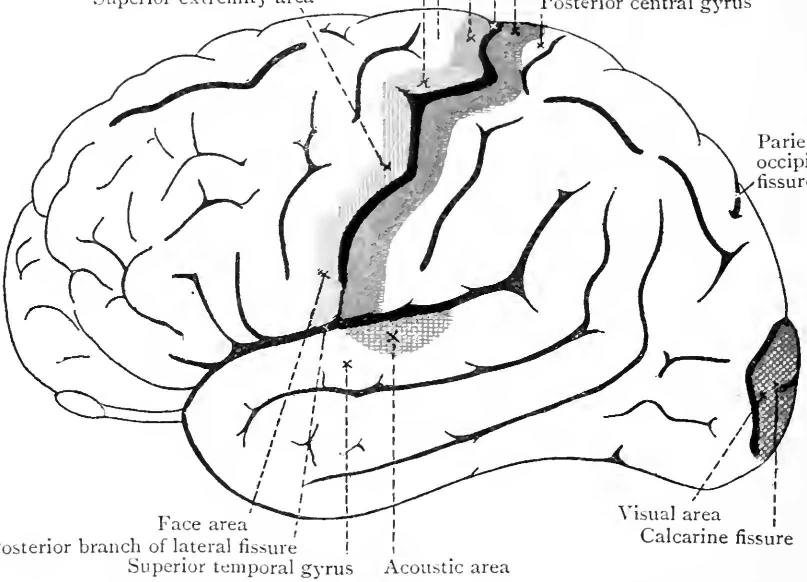

FIG. 153.—Lateral aspect of Left Hemisphere, showing Motor and Sensory Areas. (After Elliot Smith.)

The *frontal operculum* is the small triangular piece of cerebral cortex between the anterior ascending and horizontal branches of the lateral fissure. It is sometimes termed the *pars triangularis*.

The *orbital operculum* is for the most part on the under surface of the hemisphere. It lies below the anterior horizontal limb of the lateral fissure, and passes backwards from the orbital aspect of the frontal lobe over the anterior part of the insula.

Sulcus Centralis (O.T. **Fissure of Rolando**).—The central sulcus runs obliquely across the supero-lateral surface of the

hemisphere, somewhat nearer the posterior than the anterior end. It lies between two gyri which, though they are obliquely placed, are still the most vertical gyri on the supero-lateral surface, and it separates the frontal from the parietal lobe. The upper end of the sulcus frequently cuts the supero-medial border of the hemisphere, and, in such cases, it appears on the medial surface of the hemisphere. The lower end, as a rule, is separated from the posterior ramus of the lateral fissure by a small bounding gyrus. The sulcus does not take a straight course between its two extremities; on the contrary, it is bent upon itself several times, on account of buttress-like projections from its bounding walls (Figs. 138, 153). The two most prominent buttresses spring from the anterior wall, which is formed by the anterior central gyrus. From its upper end the sulcus runs, at first, downwards and forwards to the base of the upper buttress; then it bends, first round the upper and next round the lower buttress; finally, its lowest part runs almost vertically downwards from the base of the lower buttress. The anterior central gyrus, which forms the anterior boundary of the central sulcus, constitutes the motor region of the cerebral cortex, and by means of the buttresses which spring from its posterior face it is possible to define in a fairly accurate manner the various motor areas. The lower limb area extends from the upper end of the central sulcus to the apex of the upper buttress; the trunk area corresponds with the lower face of the upper buttress; the upper limb area corresponds with the region of the lower buttress; and the head area corresponds with the anterior boundary of the central sulcus below the lower buttress.

When the margins of the central sulcus are gently separated, a transverse annectant gyrus will be found crossing its floor and uniting together the anterior and posterior central gyri. It lies at the level of the lower part of the upper buttress of the anterior central gyrus.

Fissura Parieto-occipitalis.—The greater part of the parieto-occipital sulcus is situated on the medial surface of the cerebral hemisphere (Fig. 159); only the small lateral part appears on the supero-lateral face (Fig. 153).

The *lateral part of the parieto-occipital fissure* (O.T. *external parieto-occipital*) cuts the supero-medial border of the hemisphere, in a transverse direction, from 37.5 to 50 mm. (*one*

and a half to two inches) anterior to the occipital pole. It is about 12.5 mm. (*half an inch*) in length, and it is brought to an abrupt termination laterally by an arching gyrus, called the *arcus parieto-occipitalis*, which winds round it (Fig. 154).

The *medial part of the parieto-occipital fissure* (Fig. 159) will be seen when the medial surface of the hemisphere is studied (p. 419).

The Lobes seen on the Supero-lateral Surface of the

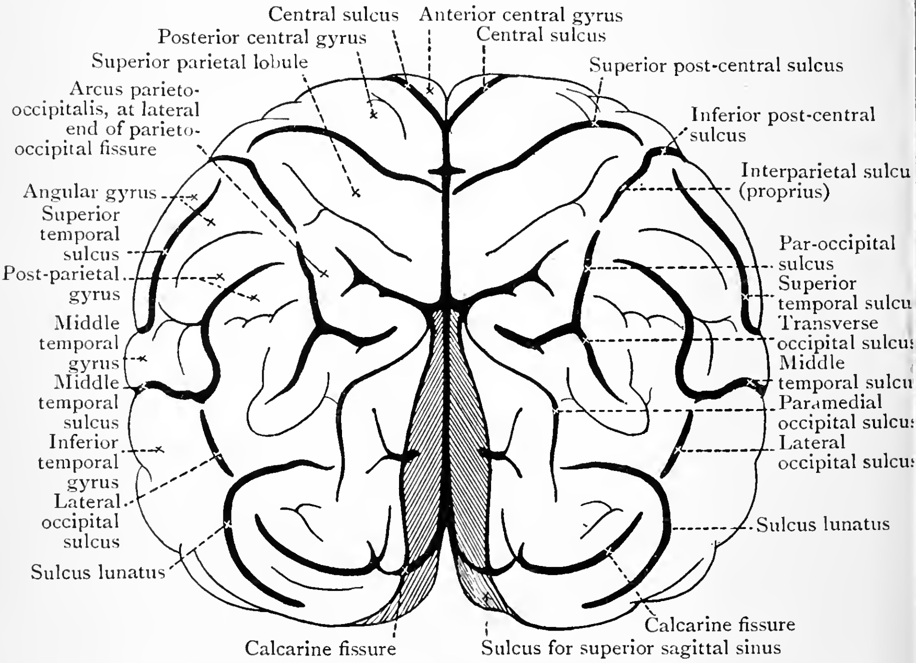

FIG. 154.—Posterior view of the Hemispheres of the Brain (semi-diagrammatic). The posterior parts of the supero-medial borders are separated and portions of the medial surfaces are seen (shaded).

Hemisphere, and the Insula.—The dissector must understand that the areas called the *lobes* of the cerebrum are defined merely for purposes of description and localisation; they do not correspond with physiological areas, nor do they correspond, exactly, in extent with the bones after which they are named. For example, the lobes which can be seen on the supero-lateral surface, without any disturbance of its parts, are the frontal, the parietal, the occipital and the temporal. It is true that all those lobes lie in relation with the bones after which they are named, but only the parietal

lobe is entirely under cover of the parietal bone; whilst, on the other hand, the parietal bone covers all the parietal lobe and parts of each of the other lobes—a considerable part of the frontal lobe, and smaller portions of the occipital and temporal lobes. Further, each of the lobes forms part not only of the supero-lateral but also, at least, of one other surface of the hemisphere, where it lies in relation with parts other than the bones after which it is named (Fig. 177).

Lobus Frontalis.—The frontal lobe appears on the supero-lateral, the inferior, and the medial surfaces of the hemisphere.

The *Supero-lateral Surface of the Frontal Lobe* is bounded, above, by the supero-medial border; below, by the superciliary border and the anterior part of the posterior ramus of the lateral fissure; and it extends, antero-posteriorly, from the frontal pole to the central sulcus. It is divided by three sulci into four chief gyri. The sulci are the precentral, and the superior and inferior frontal. The gyri are the anterior central and the superior, middle and inferior frontal.

Sulcus Præcentralis.—The precentral sulcus consists of two parts, superior and inferior: they run obliquely upwards and backwards, parallel with the central sulcus of the hemisphere, and although they are sometimes continuous in the adult they are developed independently of one another. The superior precentral sulcus is generally connected with the superior frontal sulcus. The inferior precentral sulcus has usually two limbs, a vertical, which lies parallel to the lower part of the central sulcus, and a horizontal or oblique limb which extends forwards into the middle frontal gyrus (Figs. 138, 152).

Sulcus Frontalis Superior (Figs. 138, 152).—The superior frontal sulcus extends forwards from the superior precentral sulcus.

Sulcus Frontalis Inferior (Figs. 138, 152).—The inferior frontal sulcus commences posteriorly in the angle between the vertical and the horizontal or oblique part of the inferior precentral sulcus, and, not uncommonly, it is confluent with one or other of the two parts. As it passes forwards it descends towards the superciliary border and ends a short distance from it in a terminal bifurcation.

Gyrus Centralis Anterior.—The anterior central gyrus extends, obliquely, across the supero-lateral surface of the hemisphere, from the supero-medial border above, to the

posterior ramus of the lateral fissure, below. It lies between the central and the precentral sulci and is the region of the motor area of the brain. It is continuous, at its upper and its lower ends, round the extremities of the central sulcus, with the posterior central gyrus. From its posterior face two buttresses, an upper and a lower, project backwards, as pointed out on p. 403. The buttresses form excellent landmarks for the delimitation of the parts of the motor area. Anteriorly, the anterior central gyrus is continuous with the superior, middle, and inferior frontal gyri, and, inferiorly, it forms part of the fronto-parietal operculum (p. 401). Its lower two-thirds are supplied by the middle cerebral artery, and its upper third is supplied by the anterior cerebral artery (Fig. 148).

Gyrus Frontalis Superior.—The superior frontal gyrus lies above the superior frontal sulcus. It forms also part of the supero-medial border and part of the medial surface of the hemisphere. It is continuous, posteriorly, with the anterior central gyrus, and, anteriorly, round the frontal pole, with the gyrus rectus and the medial orbital gyrus of the inferior surface of the frontal lobe. The supero-lateral part of the superior frontal gyrus is frequently divided into upper and lower parts by an interrupted furrow called the *paramedial frontal sulcus* (Fig. 137).

Gyrus Frontalis Medius.—The middle frontal gyrus lies between the superior and inferior frontal sulci. It is continuous, posteriorly, with the anterior central gyrus, and, round the superciliary border, with the anterior orbital gyrus of the inferior surface of the frontal lobe. The horizontal or oblique limb of the inferior precentral sulcus cuts into its posterior end (Fig. 138).

Gyrus Frontalis Inferior.—The centre for speech has been associated with the posterior part of the inferior frontal gyrus of the left side; therefore the inferior frontal gyrus is a region of special interest. It extends forwards, from the inferior precentral sulcus, and is continuous, round the superciliary border, with the lateral and posterior orbital gyri of the inferior surface of the frontal lobe. The inferior frontal gyrus is divided into three parts by the anterior ascending and the anterior horizontal rami of the lateral fissure. The posterior part is sometimes called the *pars basilaris*; it lies between the anterior ascending ramus of the

lateral fissure and the inferior precentral sulcus, and is continuous, posteriorly, with the anterior central gyrus. The middle part, called also the *pars triangularis*, lies between the anterior ascending and the anterior horizontal rami of the lateral fissure. The anterior part, which has been termed the *pars orbitalis*, is placed below and anterior to the anterior horizontal ramus of the lateral fissure, and it is continuous with the posterior orbital gyrus of the inferior surface (Fig. 152).

Additional Sulci of the Supero-lateral Surface of the Frontal Lobe.—There are four fairly constant sulci on the supero-lateral surface of the frontal lobe, besides those which intervene between its principal gyri; they are the paramedial, the middle, the fronto-marginal, and the diagonal.

The *paramedial sulcus* is either a continuous sulcus which lies between the supero-medial border and the superior frontal sulcus, and separates the superior frontal gyrus into upper and lower parts, or it is represented by a series of separate depressions (Fig. 137).

The *middle frontal sulcus* separates the middle frontal gyrus into upper and lower parts. It terminates anteriorly, close to the superciliary border of the hemisphere, in a transversely placed limb called the *fronto-marginal sulcus* (Fig. 152).

The *diagonal sulcus* lies parallel with the inferior part of the inferior precentral sulcus, in the posterior part of the inferior frontal gyrus, intervening between two structurally different parts of that portion of the gyrus.

The *Inferior Surface of the Frontal Lobe* forms the orbital or anterior part of the inferior surface of the hemisphere. It rests upon the roof of the orbit and the roof of the nose. It is bounded, anteriorly and laterally, by the superciliary border, and, medially, by the medial orbital border. Posteriorly, in the lateral part of its extent, its boundary is the stem of the lateral fissure, but, more medially, it is separated from the anterior perforated substance by a sulcus which has been named the *fissura prima*.

The *Sulci of the Inferior Surface of the Frontal Lobe* are the olfactory sulcus and the orbital sulci (Fig. 138).

Sulcus Olfactorius.—The olfactory sulcus lies parallel with, and a short distance from, the medial orbital border. It lodges the olfactory bulb and the olfactory tract.

Sulci Orbitales.—The orbital sulci are irregular in arrangement, but generally they assume, collectively, a somewhat H-shaped form, the transverse bar of the H being at right angles to the long axis of the hemisphere.

The *Gyri of the Inferior Surface of the Frontal Lobe* are the gyrus rectus and the orbital gyri.

Gyrus Rectus.—The gyrus rectus is the district medial to the olfactory sulcus, and it extends from the frontal pole to

the anterior perforated substance. It is continuous, round the frontal pole, with the superior frontal gyrus, and it turns round the medial orbital border on to the medial surface of the hemisphere.

Gyri Orbitales.—The orbital gyri are medial, lateral, anterior and posterior. The medial and lateral are continuous with the anterior and posterior, both anteriorly and posteriorly.

The medial orbital gyrus lies between the olfactory sulcus and the medial limb of the H-shaped sulcus. The anterior and the posterior orbital gyri are respectively anterior and posterior to the transverse bar of the H-shaped sulcus; and the lateral gyrus is to the lateral side of the lateral limb of the sulcus.

The medial orbital gyrus is continuous with the superior frontal gyrus; the anterior orbital gyrus is in continuity with the middle frontal gyrus; and the lateral orbital gyrus, with the inferior frontal gyrus; whilst at the bottom of the stem of the lateral fissure the posterior orbital gyrus is separated from the temporal lobe by the lower part of the insula.

The medial surface of the frontal lobe will be examined at a later period; but the dissector should note that upon its medial surface are a part of the superior frontal gyrus, a part of the gyrus cinguli and a part of the paracentral lobule (Fig. 159).

Lobus Parietalis.—The parietal lobe appears on the supero-lateral and the medial surfaces of the hemisphere, and its lower portion forms the upper wall of the posterior horizontal ramus of the lateral fissure. The part on the medial surface which forms the precuneus, and takes part in the formation of the paracentral lobule and the gyrus cinguli, will be examined at a later period. The inferior portion partly abuts against the temporal lobe, along the superficial part of the posterior ramus of the lateral fissure, but, more deeply, it is in close relation with the insula, from which it is separated by the circular sulcus. The dissector should verify these facts by gently separating the lips of the posterior ramus of the lateral fissure.

The *Supero-lateral Surface of the Parietal Lobe* lies entirely under cover of the parietal bone, and is bounded, above, by the supero-medial border of the hemisphere; below, by the posterior ramus of the lateral fissure and by a line projected horizontally backwards from the point where that fissure turns

upwards; anteriorly, by the central sulcus; and, posteriorly, by the lateral part of the parieto-occipital fissure and a line prolonged from it to the pre-occipital notch on the infero-lateral border of the hemisphere (Figs. 155, 177).

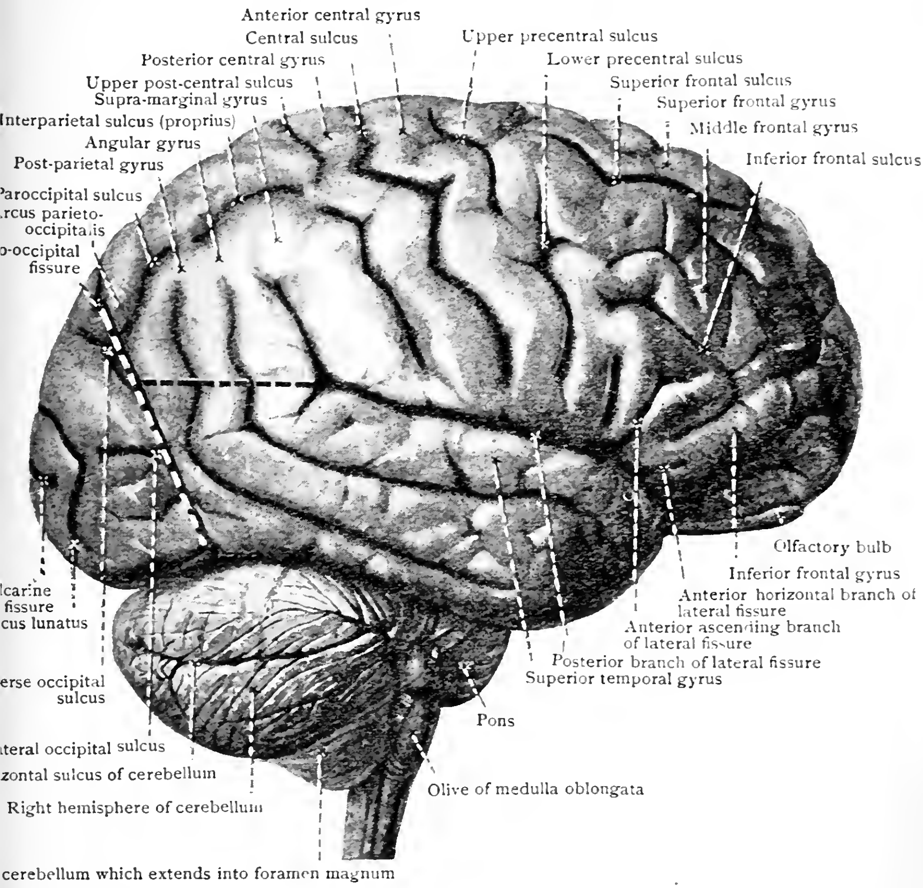

FIG. 155.—Lateral surface of Right Half of the Brain (semi-diagrammatic). The horizontal dotted line completes the separation between the parietal and temporal areas, and the oblique dotted line, which runs from the parieto-occipital fissure to the pre-occipital notch, separates the occipital from the parietal and temporal areas.

The Sulci of the Supero-lateral Surface of the Parietal Lobe.—The sulci of the supero-lateral surface of the parietal lobe are the post-central sulci, the interparietal sulcus proper, and the par-occipital sulcus.

Sulci Postcentrales.—There are two post-central sulci—a superior and an inferior. They are developed independently,

and they run parallel with the central sulcus, from which they are separated by the posterior central gyrus. Not uncommonly, the two post-central sulci are continuous with one another in the adult; and either the one or the other may be continuous with the sulcus interparietalis proprius (Figs. 152, 155).

Sulcus Interparietalis Proprius.—The interparietal sulcus proper runs backwards, almost horizontally, about midway between the upper and lower borders of the supero-lateral surface of the parietal lobe. It separates the superior from the inferior parietal lobule, and it may be continuous, anteriorly, with one or other of the post-central sulci, and, posteriorly, with the par-occipital sulcus.

Sulcus Paroccipitalis.—In the adult, the par-occipital sulcus is either directly continuous with, or it commences close to, the posterior end of the sulcus interparietalis proprius. It runs backwards, past the lateral end of the parieto-occipital fissure, from which it is separated by a parieto-occipital annectant gyrus called the arcus parieto-occipitalis; and it terminates, in the occipital lobe, in the transverse occipital sulcus (Figs. 137, 152, 154).

In the past it was the custom to speak of an interparietal sulcus which consisted of a vertical, a horizontal and an occipital portion. The vertical part is the inferior post-central sulcus, the horizontal part is the sulcus interparietalis proprius, and the occipital part is the par-occipital sulcus.

The Gyri of the Supero-lateral Surface of the Parietal Lobe.—The subdivisions of the supero-lateral surface of the parietal lobe are the posterior central gyrus; the superior parietal lobule; and the supra-marginal, the angular, and the post-parietal gyri, which form collectively the inferior parietal lobule (Fig. 152).

Gyrus Centralis Posterior.—The posterior central gyrus lies between the central and the post-central sulci. Along its anterior face, which forms the posterior wall of the central sulcus, and along the adjacent part of the supero-lateral surface lies the main area of ordinary sensation (Fig. 153). It is continuous, above and below, with the anterior central gyrus, and posteriorly with the superior and inferior parietal lobules.

Lobulus Parietalis Superior.—The superior parietal lobule is bounded, anteriorly, by the superior post-central sulcus; posteriorly, by the parieto-occipital fissure; above, by the supero-medial border; and, below, by the sulcus interparietalis

proprius. It is sometimes divided into anterior and posterior parts by a small sulcus called the *superior parietal sulcus.*

Lobulus Parietalis Inferior.—The anterior and the superior boundaries, and the anterior part of the inferior boundary of the inferior parietal lobule are quite definite, but the posterior boundary and the posterior part of the inferior boundary are arbitrary lines. The superior boundary is the sulcus interparietalis proprius; the anterior boundary is the inferior post-central sulcus; the inferior boundary is formed by the posterior part of the posterior ramus of the lateral fissure, and an imaginary line drawn backwards from the point where the posterior ramus of the lateral fissure turns upwards, to a second imaginary line, drawn from the lateral part of the parieto-occipital fissure to the pre-occipital notch on the infero-lateral border. The last-mentioned line, and the lateral part of the parieto-occipital fissure form the posterior boundary of the parietal lobe, and separate it from the occipital lobe (Fig. 155).

The Sulci of the Inferior Parietal Lobule are the upturned ends of the posterior ramus of the lateral fissure, and the superior and middle temporal sulci, which extend from the temporal lobe into the inferior parietal lobule (Fig. 152).

The Gyri of the Inferior Parietal Lobule are three in number —the supra-marginal, the angular, and the post-parietal.

The *supra-marginal gyrus* surrounds the upturned end of the posterior ramus of the lateral fissure.

The *angular gyrus* surrounds the upturned end of the superior temporal sulcus; and, in a similar manner, the *post-parietal gyrus*, when it is well marked, surrounds the upturned end of the middle temporal sulcus. It is separated from the arcus parieto-occipitalis by the sulcus par-occipitalis.

Lobus Temporalis.—The temporal lobe appears on the lateral and the inferior surfaces of the hemisphere, and it forms the lower wall of the posterior ramus of the lateral fissure.

The Sulci on the Lateral Surface of the Temporal Lobe are the superior and the middle temporal sulci.

Sulcus Temporalis Superior.—The superior temporal sulcus lies parallel with the posterior ramus of the lateral fissure (Figs. 152, 155). It intervenes between the superior and the middle temporal gyri; and it consists of two genetically distinct portions—an anterior and a posterior, which sometimes remain separate, even in the adult.

Sulcus Temporalis Medius.—The middle temporal sulcus, which lies between the middle and the inferior temporal gyri, is very irregular in its mode of formation; not infrequently it is represented by two or more separate portions.

The Gyri of the Lateral Surface of the Temporal Lobe.—There are three gyri on the lateral surface of the temporal lobe—superior, middle, and inferior.

Gyrus Temporalis Inferior.—The inferior temporal gyrus lies below the middle temporal sulcus; it forms the temporal part of the infero-lateral border of the hemisphere, and will be seen again on the inferior surface of the temporal lobe, where it is separated from the fusiform gyrus by the inferior temporal sulcus.

Gyrus Temporalis Medius.—The middle temporal gyrus lies between the middle and the superior temporal sulci, and it is more or less continuous, posteriorly, with the angular and the post-parietal gyri.

Gyrus Temporalis Superior.—The superior temporal gyrus lies between the superior temporal sulcus and the posterior ramus of the lateral fissure, and it extends forwards to the tip of the temporal pole of the hemisphere (Fig. 152).

The Upper Part of the Temporal Lobe, which forms the lower wall of the posterior ramus of the lateral fissure, is in relation with the insula and the lower parts of the parietal and frontal lobes. The dissector can display it by gently separating the lips of the fissure, and upon it two gyri, running backwards and medially, will be seen; they are the *anterior transverse temporal gyrus* (Heschl's convolution) and the *posterior transverse temporal gyrus*. The anterior transverse temporal gyrus and the portion of the posterior part of the superior temporal gyrus adjacent to its lateral end constitute the *acoustic area* of the brain cortex (Fig. 153).

The Inferior Surface of the Temporal Lobe forms the greater part of the posterior portion of the inferior surface of the hemisphere, and in brains hardened *in situ* it is marked, anteriorly, by an obvious depression due to the eminentia arcuata of the anterior surface of the petrous part of the temporal bone.

The Fissures and Sulci of the Inferior Surface of the Temporal Lobe are: (1) part of the chorioidal fissure (Fig. 138); (2) the collateral fissure; (3) the stem of the calcarine fissure; (4) the rhinal fissure; and (5) the inferior temporal sulcus.

Fissura Chorioidea.—The chorioidal fissure forms the anterior portion of the medial or upper boundary of the posterior part of the inferior surface of the hemisphere. In the region of the fissure the wall of the cavity of the hemisphere is reduced to a thin layer of epithelium, and the fissure is produced by the invagination of the epithelial wall, into the inferior cornu of the lateral ventricle of the hemisphere, by a vascular fold of pia mater.

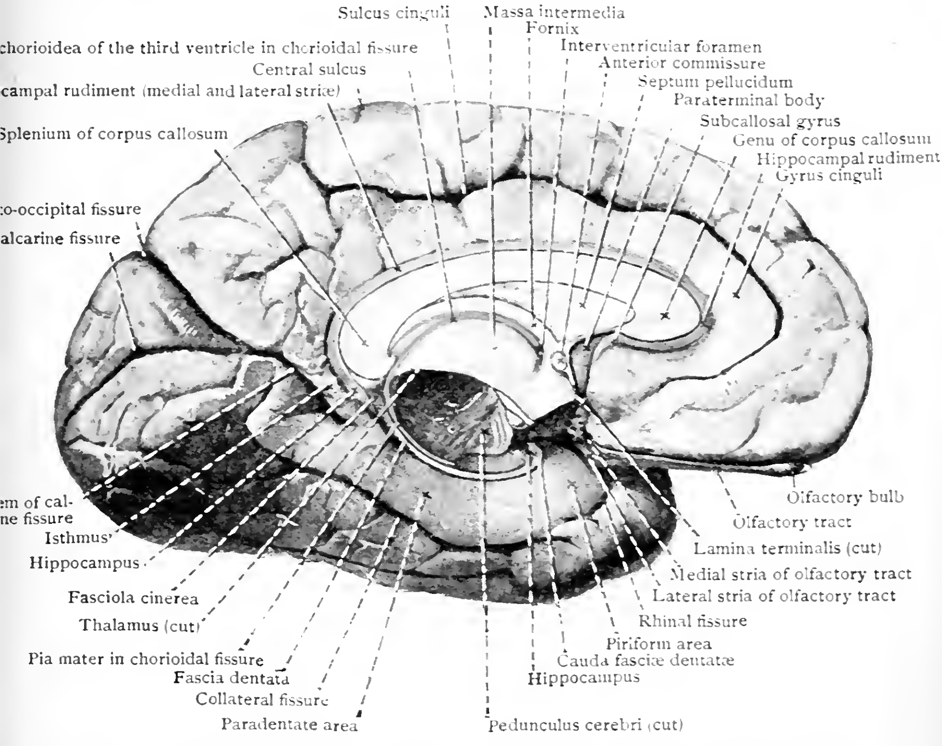

FIG. 156.—Diagram showing portions of the Hippocampus and associated parts. The green line represents the indusium, which is a rudiment of the hippocampal formation.

Below the posterior part of the chorioidal fissure the stem of the *calcarine fissure* reaches the inferior surface, after cutting across the medial occipital border of the hemisphere.

Fissura Collateralis.—The collateral fissure is placed more laterally and on a lower level than the chorioidal fissure. It lies below the stem of the calcarine fissure and extends forwards beyond its anterior extremity (Figs. 156, 159).

The Rhinal Fissure lies anterior to and slightly above or medial to the anterior end of the collateral fissure.

Sulcus Temporalis Inferior.—The inferior temporal sulcus is below and lateral to the collateral fissure.

The Gyri of the Inferior Surface of the Temporal Lobe are the hippocampal gyrus, the lingual gyrus, the fusiform gyrus, and a part of the inferior temporal gyrus.

Gyrus Hippocampi.—The hippocampal gyrus is bounded by the rhinal and collateral fissures, infero-laterally, and the chorioidal fissure, supero-medially. The posterior end of the hippocampal gyrus is continuous, below the stem of the calcarine fissure, with the anterior part of the lingual gyrus, and, in front of the anterior end of the calcarine fissure, it is connected by means of a narrow bridge, called the *isthmus*, with the posterior part of the gyrus cinguli, which embraces the corpus callosum, and which forms, with the isthmus and the hippocampal gyrus, a continuous fold of the cortex termed the *gyrus fornicatus.* The anterior end of the hippocampal gyrus is turned upwards and backwards, and is called the *uncus* (Fig. 138).

If the upper or medial border of the hippocampal gyrus, behind the uncus, is displaced downwards a vertically notched ridge of grey matter will be brought into view; it is the *fascia dentata*, and it will be seen to much better advantage when the inferior cornu of the lateral ventricle is studied. The portion of the hippocampal gyrus which lies above and medial to the rhinal fissure, including the uncus, is *the piriform area*, and it is closely associated with the sensation of smell. The more posterior part of the hippocampal gyrus forms the *paradentate area* (Fig. 156).

Gyrus Lingualis.—The portion of the lingual gyrus which appears on the inferior surface of the temporal lobe lies between the stem of the calcarine fissure and the posterior part of the collateral fissure (Figs. 138, 159). It is continuous anteriorly with the hippocampal gyrus, and, posteriorly, its upper part crosses the medial occipital border of the hemisphere and forms part of the medial surface of the occipital lobe. It constitutes a portion of the striate area or area of vision.

Gyrus Fusiformis.—The fusiform gyrus lies between the collateral fissure and the inferior temporal sulcus. It is continued posteriorly to the inferior surface of the occipital lobe.

Gyrus Temporalis Inferior.—Only a part of the inferior temporal gyrus appears on the inferior surface of the temporal

lobe; the remainder forms the infero-lateral border of the hemisphere, in the temporal region, and a part of the lateral surface of the temporal lobe.

Lobus Occipitalis.—The occipital lobe forms part of the supero-lateral, part of the inferior, part of the medial surface of the hemisphere, and the occipital pole. Its medial surface, which will be seen more clearly at a later stage, is definitely separated from the medial surface of the parietal lobe by the parieto-occipital fissure. The boundary which separates its supero-lateral surface from the adjacent parts of the parietal and temporal lobes is the small, lateral part of the parieto-occipital fissure, and a line drawn from that fissure to the pre-occipital notch on the infero-lateral border of the hemisphere. It is, therefore, largely artificial; and there is no natural line of demarcation between the inferior surface of the occipital lobe and the inferior surface of the temporal lobe (Figs. 138, 156, 159).

The Sulci and Fissures of the Supero-lateral Surface of the Occipital Lobe.—On the posterior part of the supero-lateral surface of the occipital lobe is the terminal part of the *calcarine fissure* which curls round the occipital pole, from the medial to the lateral surface. The portion of the brain cortex which immediately surrounds the extremity of the calcarine fissure is part of the striate or visual area of the cortex (Figs. 152, 154, 155).

Immediately anterior to the end of the calcarine fissure is a curved sulcus, convex forwards, called the *sulcus lunatus*. It forms the anterior boundary of the visual area on the supero-lateral surface of the hemisphere. Anterior to the sulcus lunatus, and at right angles with it, is the *sulcus occipitalis lateralis*, which divides the larger, anterior part of the supero-lateral surface of the occipital lobe into an upper and a lower portion. Passing backwards from the parietal lobe into the upper portion of the occipital lobe is the sulcus par-occipitalis. It ends posteriorly in a sulcus, the *sulcus occipitalis transversus*, which is at right angles with the sulcus par-occipitalis. In some cases a small sulcus, the *sulcus occipitalis paramedialis*, is recognisable, parallel with and close to the supero-medial border of the occipital lobe (Figs. 152, 154). When it is present the supero-lateral surface of the occipital lobe is separated, by it and the lateral occipital sulcus, into superior, middle, and inferior gyri.

The Sulci and Gyri of the Inferior Surface of the Occipital Lobe.—The posterior part of the collateral fissure extends backwards from the temporal into the occipital lobe, separating the lingual gyrus from the posterior part of the fusiform gyrus, both of which enter into the formation of the inferior surface of the occipital lobe (Figs. 138, 156).

After the study of the fissures, sulci, and gyri of the superolateral and inferior surfaces of the hemispheres is completed

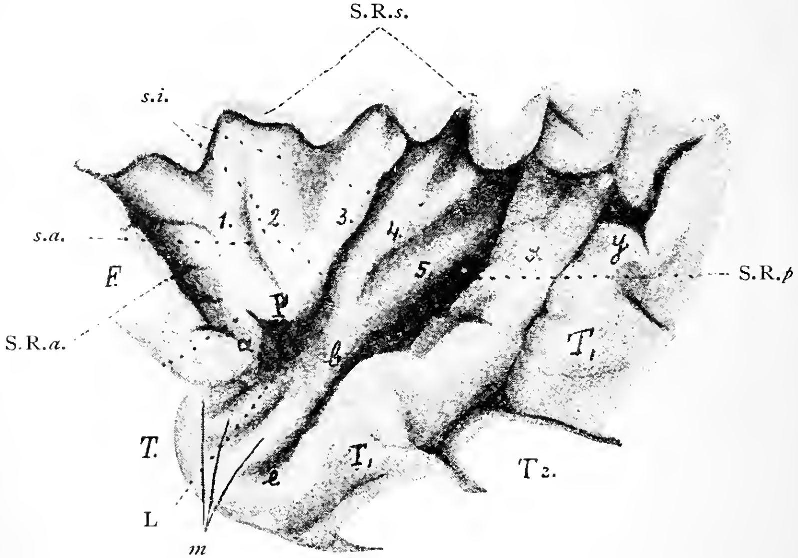

FIG. 157.—Fissures and Gyri on the Surface of the Insula. (Eberstaller.)

1, 2, and 3. Three short gyri on the frontal part of the insula.

m. Gyri on deep surface of temporal pole.

the dissector should separate the margins of the lateral fissure from one another, and examine the insula, which lies under cover of the boundaries of the fissure; or if the brain is so hardened that the margins of the fissure cannot be drawn apart the dissector should cut away the portions of the frontal, parietal, and temporal lobes which overlap and conceal the insula.

Insula (O.T. **Island of Reil**).—The insula is a pyramidal area of the hemisphere which lies on a deeper plane than the remainder of the surface of the hemisphere; it is hidden from view by the adjacent margins of the frontal, parietal, and temporal lobes, which overlap it and constitute the opercula of the *fossa lateralis*. The fossa lateralis is the depression, at the bottom of the lateral fissure, in which the insula lies. Round the anterior, superior, and posterior borders of the insula runs a sulcus, called the *sulcus circularis*. It separates the insula from the adjacent parts of the hemisphere. At the apex or lowest part of the insula there is a rounded fold of the brain substance; it is directly connected with the lateral of the two striæ which extend from the posterior end of the olfactory tract and with the piriform area of the hippocampal gyrus, and it forms part of the olfactory area of the hemisphere. The region in which it is situated is known as the *limen insulæ*.

The surface of the insula is divided into an anterior or frontal portion and a posterior or parietal portion by the *sulcus centralis insulæ*, which is in a plane parallel with the plane of the central sulcus on the supero-lateral surface of the hemisphere. On both portions of the insula there are two or more gyri.

At this stage, the dissector should study the portion of the middle cerebral artery which was left *in situ* when the membranes were removed from the hemisphere (p. 387). He will find that it passes along the stem of the lateral fissure, crosses the limen insulæ, and breaks up on the surface of the insula into the terminal branches which were noted on the supero-lateral surface of the hemisphere (p. 388).

When the positions of the terminal branches of the middle cerebral artery have been studied, the vessels and the surrounding membranes may be removed.

Lobus Olfactorius.—Each olfactory lobe consists of several parts; they are: (1) the olfactory bulb; (2) the olfactory tract; (3) the olfactory striæ, medial and lateral; and (4) the olfactory trigone. The *olfactory bulb*, which is the most anterior part of the olfactory region of the brain, lies on the lower surface of the frontal lobe, in the anterior part of the olfactory sulcus. On its lower surface it receives the olfactory nerves, which arise in the olfactory mucous membrane of the nose and terminate in the olfactory bulb. They

are about twenty in number. The olfactory bulb is continuous, posteriorly, with the *olfactory tract*, a triangular prismatic band which runs backwards, in the olfactory sulcus, to the anterior border of the anterior perforated substance, where it ends in a pyramidal elevation, the *trigonum olfactorium*. From the lateral angle of the olfactory trigone the *stria olfactoria lateralis* passes, backwards and laterally, along the lateral margin of the anterior perforated substance and across the limen insulæ to the piriform area of the hippocampal gyrus (Fig. 162). The dissector should understand that under cover of the lateral olfactory stria there is a layer of grey matter which represents the anterior part of the piriform area.

Dissection.—To display the course of the lateral olfactory stria it will be necessary to raise the temporal pole and, possibly, it may be necessary to cut away the tip of the temporal lobe ; but that must be done on one side only.

From the medial angle of the olfactory trigone the *medial olfactory stria* passes round the posterior end of the gyrus rectus to the medial aspect of the hemisphere, towards the *subcallosal gyrus*. The subcallosal gyrus is situated on the under surface of the anterior part of the corpus callosum, and it must be looked for at a later stage of the dissection (Figs. 156, 159).

Dissection.—A dissection should now be made with the object of displaying the upper surface of the corpus callosum. For that purpose the upper portion of the hemisphere, on one side, must be removed, and when that is done it will be possible to study the gyri, fissures, and sulci on the medial surface of the opposite hemisphere.

With a long knife slice off the upper part of the right hemisphere down to the level of the sulcus cinguli on the medial surface (see Fig. 161). The white medullary centre of the hemisphere, enclosed within the grey cortex, which is brought into view when the section is made, is termed the *centrum semi-ovale*. From the centrum semi-ovale prolongations of the white matter pass into all the surrounding gyri (Fig. 161).

A transverse incision must now be made through the centre of the gyrus cinguli, which forms the medial boundary of the semi-oval centre; then the anterior and posterior parts of the gyrus cinguli must be torn away from the hemisphere in a lateral direction. If that is done successfully the manner in which the fibres of the corpus callosum enter the hemisphere will be demonstrated (Fig. 161).

If the student is dissecting the brain for the second time he should not use the knife at all in carrying out this dissection. The upper part of the hemisphere to the level of the gyrus cinguli should be torn off and then the gyrus cinguli may be treated in

the same manner. By that expedient the fibres of the corpus callosum may be traced into individual gyri.

Cingulum.—Examine the deep surface of the gyrus cinguli, which has been torn away, and note that a large bundle of longitudinally directed fibres is embedded in its substance. The bundle is the cingulum. It is a longitudinal association bundle, composed of several systems of fibres which run only for short distances within it and then pass into the adjacent parts of the gyrus fornicatus. It curves round the convexity of the corpus callosum, commencing, in front, at the anterior perforated substance and terminating, posteriorly, in the

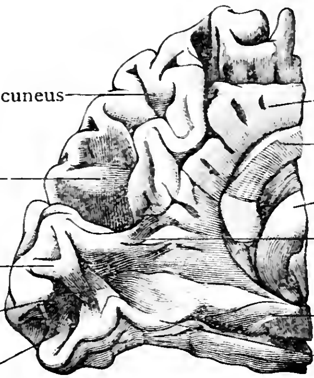

FIG. 158.—Posterior part of medial surface of the Left Hemisphere. The calcarine and the parieto-occipital fissures are widely opened up to show the deep gyri within them.

hippocampal gyrus (Fig. 156). It can be easily displaced from its bed by the exercise of a very slight degree of traction.

The fissures and sulci and gyri on the medial surface of the left hemisphere should now be studied.

The Fissures and Sulci on the Medial Surface of the Hemisphere are—the medial part of the parieto-occipital fissure; the posterior part of the calcarine fissure; the callosal sulcus; the sulcus cinguli; the subparietal sulcus; and, possibly, the upper end of the central sulcus.

Fissura Parieto-occipitalis.—The medial part of the parieto-occipital fissure descends on the posterior part of the medial surface of the hemisphere between the occipital and parietal lobes. It terminates a short distance behind the posterior end of the corpus callosum, and close to the medial occipital border, by joining the calcarine fissure. If the dissector

separates the margins of the fissure he will be able to convince himself that the union of the two fissures occurs only near the surface, and that the lower end of the deep part of the parieto-occipital fissure is separated from the calcarine fissure by a submerged ridge called the *gyrus cunei*.

Fissura Calcarina.—The stem or anterior part of the calcarine fissure has already been seen on the inferior surface of the hemisphere (p. 413). It crosses the medial occipital border and joins the parieto-occipital fissure on the medial surface of the occipital lobe. Then it passes backwards to the occipital pole, round which it turns; and it ends, on the supero-lateral surface of the occipital lobe, in a terminal bifurcation. If the dissector separates the margins of the fissure he will find that, immediately behind its union with the parieto-occipital fissure, a submerged ridge, the *cuneo-lingual gyrus*, separates the anterior from the posterior portion of the calcarine fissure. The ridge is an indication that the two parts of the calcarine fissure arose separately and became combined at a later period both ontogenetically and phylogenetically.

At this stage the dissector should make a frontal section through the posterior part of the right occipital lobe, and then examine the surface of the section of the grey matter in the region of the posterior part of the calcarine fissure. If the brain substance is in a state of good preservation he will find a distinct white line, called the *stria Gennari*, which cuts the grey matter into inner and outer parts, and which is not present in the neighbouring regions. The portion of the cortex marked by the line is called the *area striata*; it is the visual area of the cortex, and the line indicates that the portion of the cortex in which it lies is associated with sight. It is found in both walls of the posterior part of the calcarine fissure and the adjacent parts of the cuneus and the lingual gyrus which bound the fissure, but it occurs only on the lower lip of the anterior part of the calcarine fissure, which is situated, therefore, on the boundary line between the visual and non-visual portions of the cortex.

Sulcus Corporis Callosi.—The callosal sulcus runs round the convex outline of the corpus callosum, separating the corpus callosum from the gyrus cinguli.

Sulcus Cinguli.—The sulcus cinguli runs parallel with the callosal sulcus and is separated from it by the gyrus cinguli.

It commences below the anterior end of the corpus callosum and runs at first forwards and upwards and then backwards, parallel with the supero-medial border of the hemisphere, to a point somewhat behind the upper end of the posterior central gyrus, where it turns upwards, cuts the supero-medial border, and terminates on the supero-lateral surface of the hemisphere. It separates the gyrus cinguli, which embraces the anterior and upper parts of the corpus callosum, from the superior frontal gyrus and the upper ends of the anterior and the posterior central gyri (Figs. 159, 160).

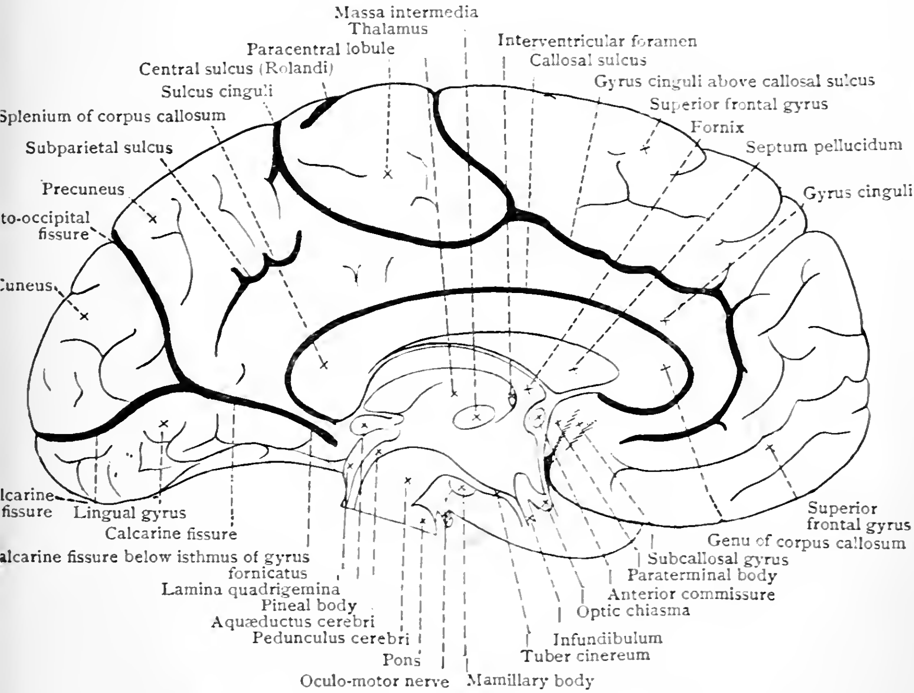

FIG. 159.—Medial surface of Left Hemisphere (semi-diagrammatic).

Sulcus Subparietalis.—Behind the posterior end of the sulcus cinguli, and sometimes continuous with it, is the subparietal sulcus. It separates the medial part of the superior parietal lobule, which is called the precuneus, from the posterior part of the gyrus cinguli (Figs. 159, 160).

The Gyri of the Medial Surface of the Hemisphere.—The gyri on the medial surface of the hemisphere are the superior frontal gyrus; the upper ends of the anterior and the posterior central gyri, the precuneus, the cuneus, part of the lingual gyrus, the gyrus cinguli, and part of the gyrus rectus.

Gyrus Frontalis Superior.—The superior frontal gyrus has been seen already on the supero-lateral surface of the hemisphere (p. 406). It forms that part of the medial surface which lies between the sulcus cinguli and the supero-medial border, and anterior to the upper end of the anterior central gyrus.

On its antero-inferior part are two or three secondary gyri which run antero-posteriorly or forwards and slightly upwards; they are known as the *rostral gyri.* The posterior end of the medial aspect of the superior frontal gyrus is separated from the upper end of the anterior central gyrus by an offshoot from the sulcus cinguli.

Lobulus Paracentralis.—The paracentral lobule corresponds in position with the upper ends of the anterior and posterior central gyri. It is bounded, posteriorly, by the upturned end of the sulcus cinguli; anteriorly, by an offset from the sulcus cinguli. Its frontal portion is part of the motor area of the cerebrum.

Præcuneus.—The precuneus is the medial part of the superior parietal lobule of the supero-lateral surface (p. 410). It is bounded, behind, by the parieto-occipital fissure; in front, by the upturned end of the sulcus cinguli; below, by the sulcus subparietalis; and, above, by the supero-medial border of the hemisphere.

Cuneus.—The cuneus forms the greater part of the medial surface of the occipital lobe. It is bounded, anteriorly, by the parieto-occipital fissure; below, by the calcarine fissure; and, above and behind, by the supero-medial border of the hemisphere.

Gyrus Lingualis.—The lingual gyrus forms the lowest part of the medial surface of the occipital lobe. On that surface it lies between the calcarine fissure and the medial occipital border, which separates the medial from the posterior part of the inferior surface of the hemisphere. Anteriorly, it crosses the medial occipital border and passes to the inferior surface, where it has already been seen (Fig. 138).

After the study of the fissures, sulci, and gyri of the medial surface of the hemisphere is completed, the dissector must remove the upper part of the left hemisphere above the level of the corpus callosum and anterior to the parieto-occipital fissure, but the fissure itself, and the part of the brain behind it, should be left intact so that a repeated study of the

calcarine fissure and its boundaries, and the relationships of the occipital and temporal lobes on the inferior surface, can be made at a later stage of the dissection.

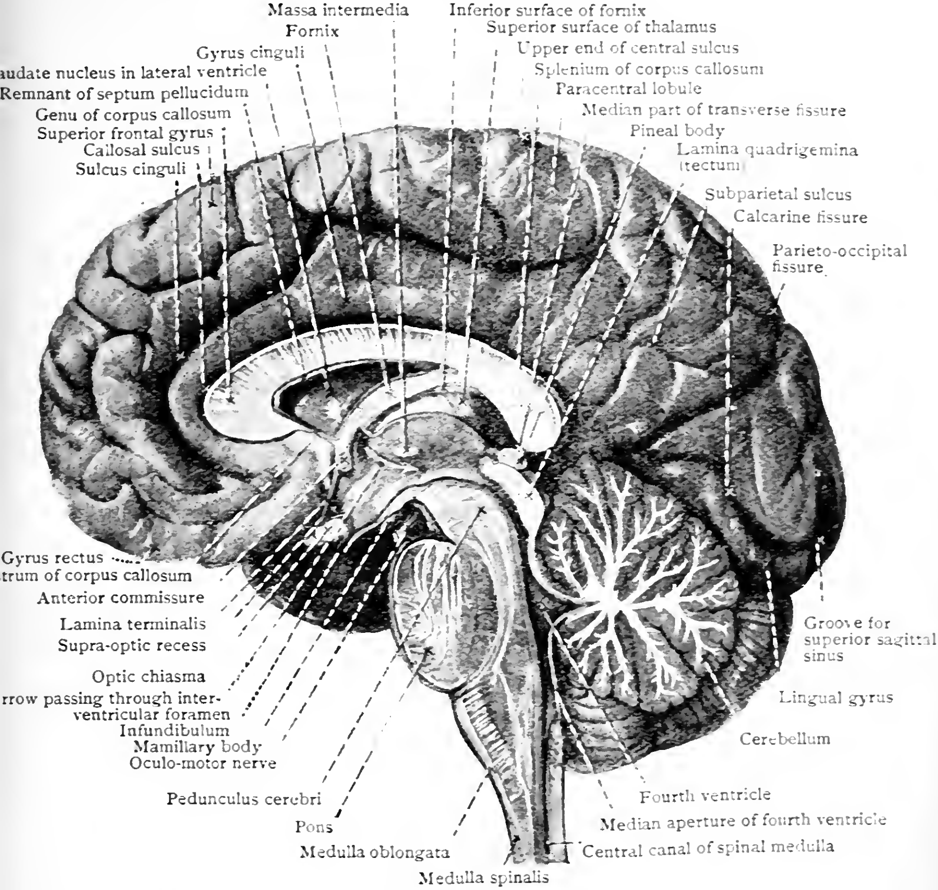

FIG. 160.—Medial surface of the Right Hemisphere, and the structures seen after a sagittal section has been made through the Corpus Callosum, the Fornix, the Diencephalon, the Mesencephalon, and the Rhombencephalon, and after the Septum Pellucidum has been removed from between the Corpus Callosum and the Fornix. The arrow passes through the interventricular foramen from the right lateral ventricle to the third ventricle, where it lies in the hypothalamic sulcus in the lateral wall of the third ventricle.

When the upper parts of both hemispheres have been removed the upper surface of the corpus callosum will be exposed; and it will be evident that the corpus callosum unites into one mass the medullary centres of the two hemispheres. The term *centrum ovale* is applied to the

continuous white area which consists of the corpus callosum and the medullary centres of the two hemispheres.

Corpus Callosum.—The corpus callosum is the great transverse commissure of the cerebrum. It is placed nearer the anterior than the posterior end of the brain, and it unites

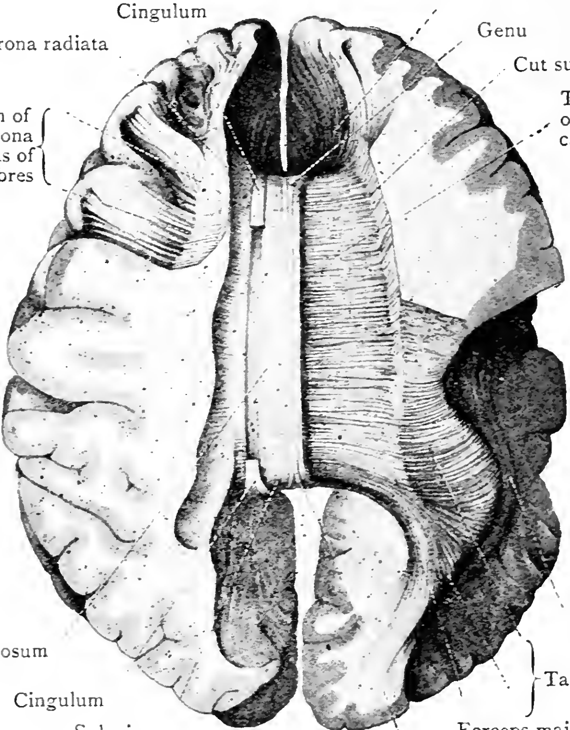

FIG. 161.—The Corpus Callosum exposed from above and the right half dissected to show the course taken by the fibres.

the medial surfaces of the two cerebral hemispheres throughout very nearly a half of their antero-posterior length (Fig. 161).

Its *upper surface*, which forms the floor of the central part of the longitudinal fissure, is convex antero-posteriorly and concave from side to side. In the posterior part of its extent it is touched, in the median plane, by the falx cerebri; anteriorly, that fold of dura mater does not pass so deeply into the fissure. On each side of the fissure the corpus callosum is covered by the gyrus cinguli (O.T. callosal gyrus). The

upper surface of the corpus callosum is coated by an exceedingly thin layer of grey matter, called the *indusium griseum*, which is continuous, at the bottom of the callosal sulcus, with the grey cortex of the hemisphere. Associated with the indusium, on each side of the median plane, are two delicate longitudinal bands of fibres called the striæ longitudinales medialis and lateralis. The *stria longitudinalis medialis* is the more strongly marked of the two, and it is separated from its fellow of the opposite side by a faint median furrow. The *stria longitudinalis lateralis* is placed more laterally. So

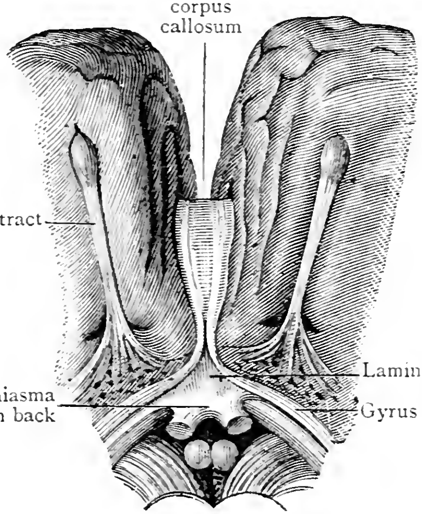

FIG. 162. — Anterior end of the Corpus Callosum and the Subcallosal Gyri as seen from below when the frontal lobes of the hemispheres are slightly separated from each other. (From Cruveilhier.)

thin is the indusium that the transverse direction of the bundles of callosal fibres can be easily seen through it.

The striæ, with the thin layer of grey matter associated with them, represent a gyrus called the *gyrus supracallosus*.

The two *extremities* of the corpus callosum (Fig. 160) are greatly thickened, whilst the middle part, the *truncus* (O.T. *body*), is considerably thinner. The thick posterior end, which is full and rounded, lies over the mesencephalon, and extends backwards as far as the highest point of the cerebellum. It is called the *splenium*. The anterior end, which is less thick than the posterior, is folded, downwards and backwards, upon itself, and is called the *genu*. The recurved lower

portion of the anterior part of the corpus callosum rapidly thins as it passes backwards, and is termed the *rostrum.* The fine terminal edge of the rostrum is connected with the lamina terminalis (Fig. 160).

Both the lateral and the medial longitudinal striæ and the indusium, which lie upon the upper surface of the corpus callosum, turn downwards, round the splenium, and become continuous, below it, with the attenuated posterior part of the *hippocampus*, a structure which will be seen, later, in the inferior horn of the lateral ventricle. Immediately above the union of the indusium with the hippocampus there is a narrow ridge of grey matter, called the *fasciola cinerea*, which is the posterior, terminal part of the fascia dentata (Fig. 156). Anteriorly, the striæ and the indusium pass round the genu, and then along the under surface of the rostrum until they terminate in the *gyrus subcallosus* of the corresponding side. The gyrus subcallosus is a ridge which descends from the rostrum of the corpus callosum and passes towards the medial olfactory stria and the substantia perforata anterior (Fig. 160).

Fibres of the Corpus Callosum.—The transverse fibres of the corpus callosum, as they enter the white medullary centre of the cerebral hemisphere, radiate from each other towards various parts of the cerebral cortex. This radiation is called the *radiatio corporis callosi.* The more anterior of the fibres which compose the genu of the corpus callosum sweep forwards, in a series of curves, towards the frontal pole of the hemisphere. They form the *forceps minor.* A large part of the splenium, forming a solid bundle termed the *forceps major*, bends suddenly and abruptly backwards into the occipital lobe. Fibres from the trunk of the corpus callosum and also from the splenium curve round the lateral ventricle and form a very definite stratum called the *tapetum.* The tapetum is a thin layer, of the medullary centre of the hemisphere, which forms the roof and lateral wall of the posterior horn, and the lateral wall of the posterior part of the inferior horn of the lateral ventricle.

Ventriculus Lateralis.

The lateral ventricle, in the interior of the cerebral hemisphere, should now be opened up on each side. The corpus callosum, which forms the roof of the central part (O.T. body) and anterior horn of this cavity, must, therefore, be partially removed.

Dissection.—Make a longitudinal incision, through the corpus callosum, about 6 mm. (*a quarter of an inch*) or less from the median plane, on each side. The central portion of the corpus callosum which lies between the incisions is to

be kept in position. The lateral portions must be turned laterally and detached completely. As that is being done, it will become evident that the lower part of the splenium, which is prolonged into the forceps major, is, in reality, a portion folded forwards in close apposition with the under surface of the posterior end of the corpus callosum. Be careful to leave the forceps major in its place (Fig. 163).

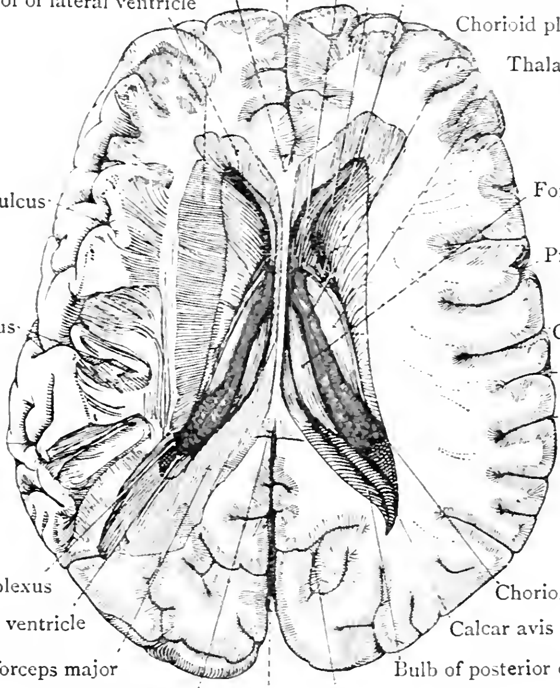

FIG. 163.—Dissection of the Lateral Ventricles of the Brain. On the right side the hemisphere was cut horizontally at the level of the junction of the lateral wall with the roof of the ventricle. On the left side the part of the hemisphere above the corpus callosum was torn obliquely away; then the corpus callosum was cut through from above.

The central part and the anterior horn of the ventricle are now exposed; but the cavity of the ventricle runs backwards into the occipital lobe in the form of a posterior horn, and downwards and forwards into the temporal lobe as the inferior horn. The posterior horn should, at present, be opened on the right side only. Carry the knife backwards through the medullary substance which forms the roof of the cavity, and remove a sufficient amount of the roof to give a complete view of the interior of the cavity. Greater difficulty will be experienced

in opening up the inferior horn. Place the point of the knife in the upper part of the horn, where it joins the central part of the ventricle, and carry the blade forwards and downwards, through the lateral part of the temporal lobe, towards the

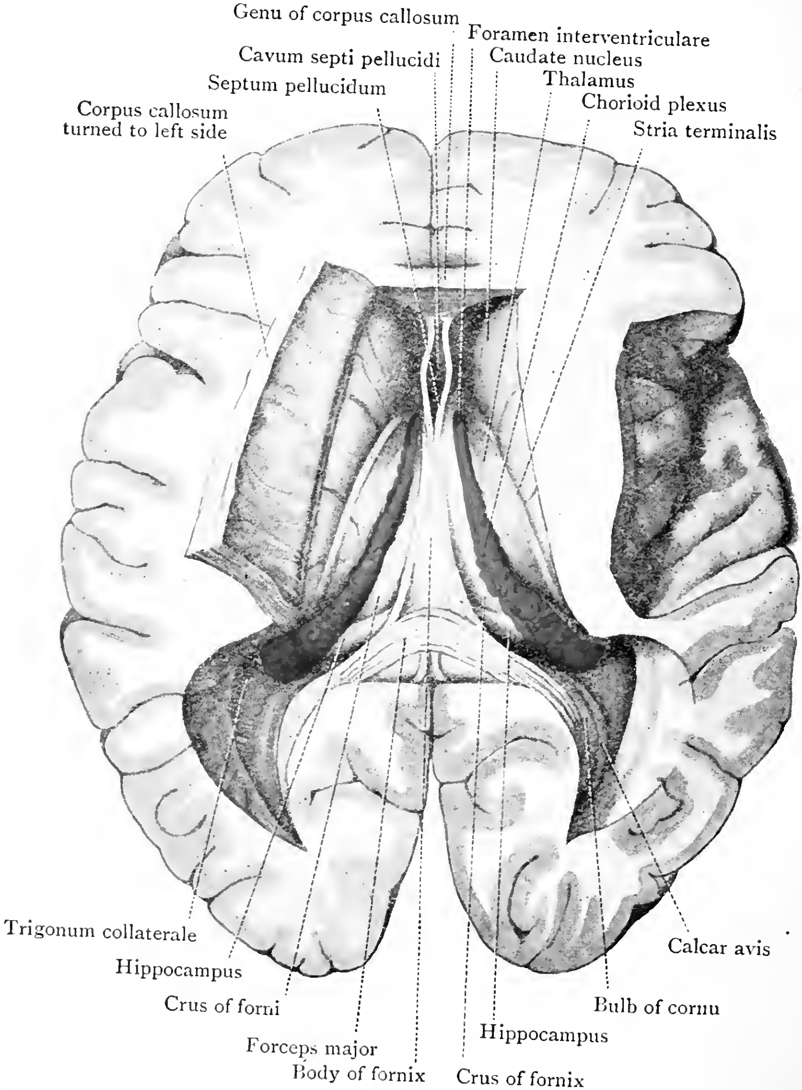

FIG. 164.—Dissection to show the Lateral Ventricles. The trunk of the corpus callosum has been detached from the genu and the splenium and turned over to the left.

temporal pole, following the course of the cavity, which corresponds, very nearly, with the course of the superior temporal sulcus. The lateral wall of the inferior horn is thus incised, and a sufficient amount of the lateral part of the temporal lobe

must be removed to give a view of the cavity. The dissection necessitates the removal of the temporal operculum, but the surface of the insula should be preserved from injury.[1]

Lateral Ventricle.—When the dissection is completed, the dissector cannot fail to note that each cerebral hemisphere is hollow. The cavity in the interior is called the lateral ventricle. It is lined with a thin dark-coloured layer of epithelium which is termed the *ependyma*. In certain places its walls are in apposition with each other, but in other

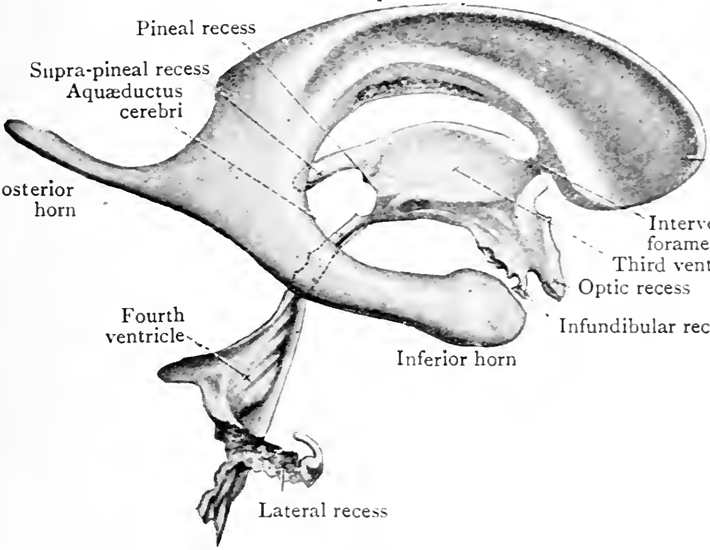

FIG. 165.—Cast of the Ventricles of the Brain. (From Retzius.)

localities spaces of varying capacity, and containing cerebro-spinal fluid, are left between the boundary walls. The lateral ventricle communicates with the third ventricle of the brain by means of a small foramen which is termed the *inter-ventricular foramen* (O.T. *foramen of Monro*) (Figs. 160, 165). That aperture, which is just large enough to admit a crow-quill, lies at the anterior end of the thalamus, and posterior to the column of the fornix (O.T. anterior pillar). To find the aperture, the dissector should note the rough fringe of vascular pia mater which lies on the floor of the ventricle, and he should follow the fringe forwards to its passage into the foramen.

The shape of the lateral ventricle is very irregular, but it

[1] If the hemispheres have already been separated from one another the dissection must be carried out on each side separately.

is readily understood when a cast of the cavity is examined (Fig. 165). It is composed of a central part (O.T. body)

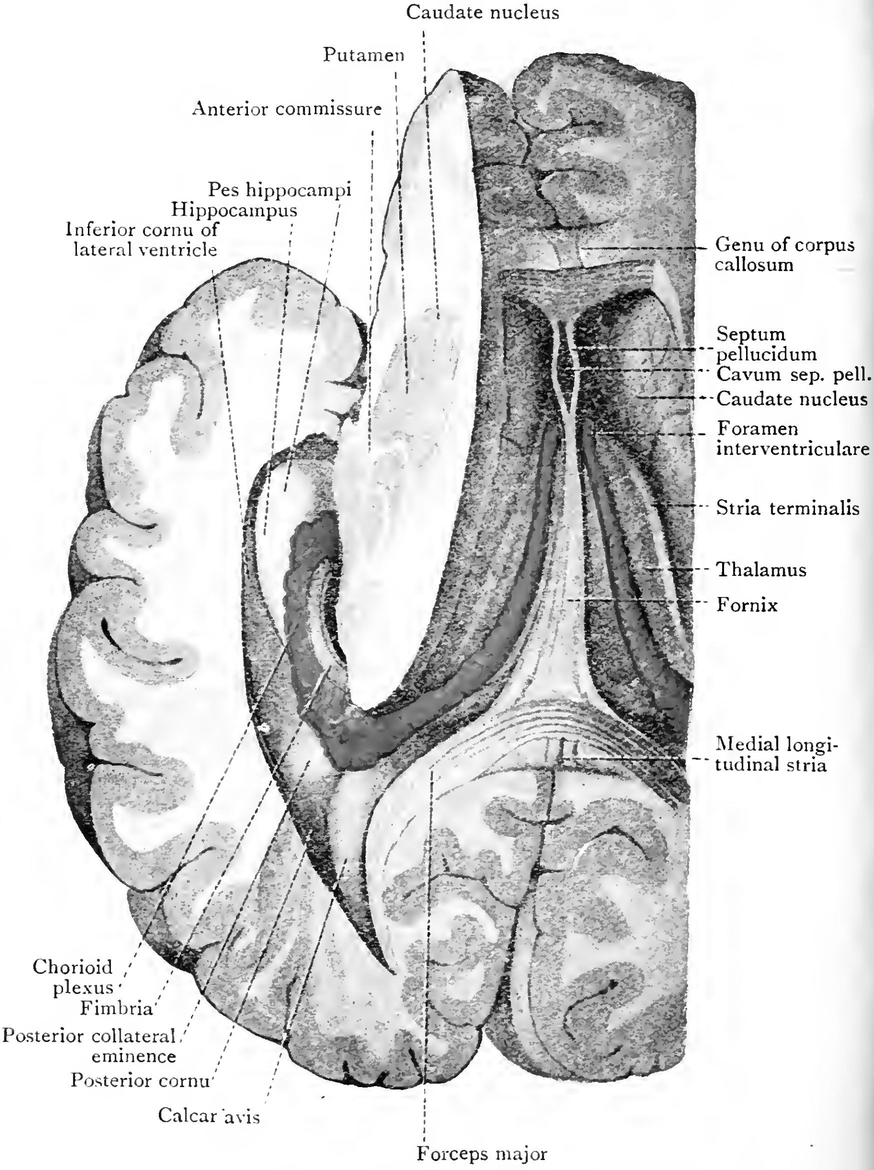

FIG. 166.—Dissection to show the Posterior and Inferior Cornua of the Lateral Ventricle on the left side.

and three horns, viz., an anterior, a posterior, and an inferior horn. The *anterior horn* is that part of the cavity which lies anterior to the interventricular foramen. The central

part is the portion of the ventricle which extends from the interventricular foramen to the splenium of the corpus callosum. At the level of the splenium the posterior and inferior horns diverge from the posterior end of the central part. The *posterior horn* curves backwards and medially into the occipital lobe. It is very variable in its length and capacity. The *inferior horn* passes, with a bold sweep, round the posterior end of the thalamus, and then tunnels, downwards and forwards, through the temporal lobe, towards the temporal pole (Fig. 166).

Behind the anterior horn the floor of the central part of the ventricle is fully exposed and the following parts should be distinguished. (1) Extending backwards and laterally from the interventricular foramen is the vascular fringe called the *chorioid plexus of the lateral ventricle.* Posteriorly it descends into the inferior horn. (2) Medial to the chorioid plexus is the upper surface of the *body of the fornix.* Its posterior extremity, on each side, becomes a crus of the fornix, which accompanies the chorioid plexus into the inferior horn, where it terminates in the fimbria of the hippocampus. (3) Lateral to the chorioid plexus is a part of the *upper surface of the thalamus.* (4) Running along the lateral margin of the thalamus, in a shallow sulcus, is a white strand called the *stria terminalis.* It descends posteriorly into the roof of the inferior horn. (5) Lateral to the stria terminalis lies the convex upper surface of the body of the caudate nucleus.

Dissection.—When the parts mentioned have been identified, the central part of the corpus callosum, which is still in position, should be carefully raised to display the *septum pellucidum*, which descends from the lower surface of the corpus callosum to the upper aspect of the fornix, and so intervenes between the lateral ventricles of the opposite sides, forming the medial wall of the central part and the anterior cornu of each ventricle. Whilst the central part of the corpus callosum is still elevated the fornix should be followed forwards. It will be found to divide into two rounded bundles, called the *columns of the fornix*, which descend, one on each side, in front of the corresponding interventricular foramen (Fig. 160).

Plexus Chorioideus Ventriculi Lateralis.—The chorioid plexus of each lateral ventricle is a plexus of blood vessels enclosed in the lateral margin of a triangular fold of pia mater called the *tela chorioidea of the third ventricle.* The body of the fold is concealed at present. It will be displayed at a later stage of the dissection (Fig. 174).

Cornu Anterius Ventriculi Lateralis.—The anterior horn forms the anterior part of the cavity, and it extends forwards, laterally and downwards in the frontal lobe. When seen in frontal section it presents a triangular outline. The floor is narrow and is formed by the white matter of the orbital part of the frontal lobe. From it the medial and lateral walls ascend to the roof, which is formed by the under surface

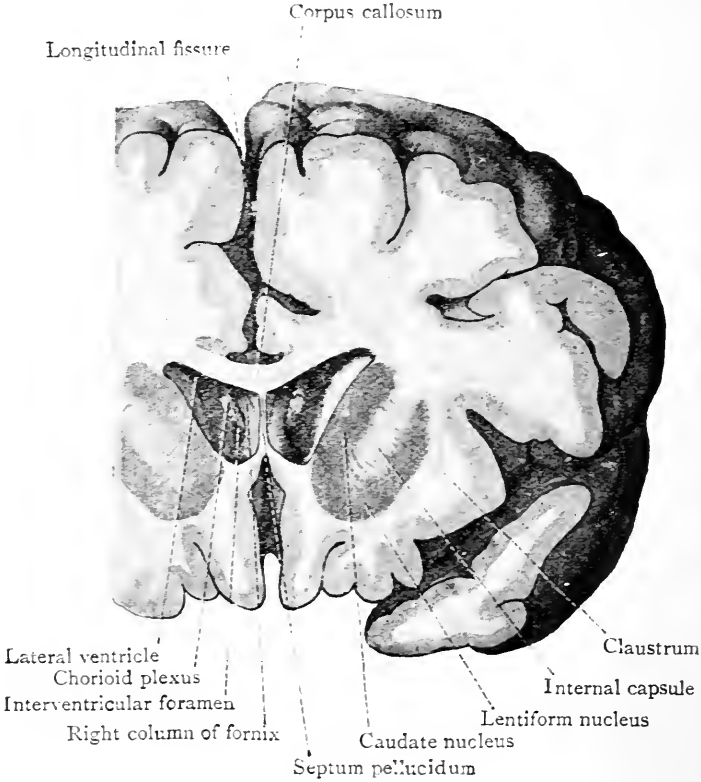

FIG. 167.—Frontal section through the Cerebrum through the anterior part of the lentiform nucleus. Seen from the anterior aspect.

of the corpus callosum. The vertical medial wall is the anterior part of the septum pellucidum, which separates the anterior horns of the opposite sides from one another. The in-bulging lateral wall is formed by the head of the caudate nucleus (Fig. 167).

Pars Centralis Ventriculi Lateralis.—The central part of the ventricle likewise is *roofed* by the corpus callosum. On the *medial side* it is bounded by the posterior part of the septum pellucidum, and more posteriorly by the attachment

of the fornix to the under surface of the corpus callosum, behind the posterior end of the septum pellucidum. On the *lateral side* it is closed by the meeting of the roof and the floor of the cavity.

In the *floor* are several important objects which have already been referred to. Latero-medially, and, at the same time, to some extent from before backwards, they are—(1) the caudate nucleus; (2) a groove extending obliquely, backwards

FIG. 168.—Frontal section showing immediate relations of Lateral and Third Ventricles. (Part of Fig. 188 enlarged.)

and laterally, between the caudate nucleus and the thalamus, in which are placed the vena terminalis (O.T. vein of corpus striatum) and a white band called the stria terminalis (O.T. tænia semicircularis); (3) a portion of the upper surface of the thalamus; (4) the chorioid plexus; (5) the thin, sharp edge of the fornix.

The *caudate nucleus* lies in the lateral part of the floor of the central part of the lateral ventricle, and it narrows very rapidly as it passes backwards.

The *vena terminalis* is seen through the ependyma in the groove between the caudate nucleus and the thalamus. It joins the internal cerebral vein (O.T. vein of Galen) at the interventricular foramen. In the same groove is placed the stria terminalis—a narrow band of white matter, which bends

downwards and disappears from view in the region of the interventricular foramen. Its fibres ultimately reach the substantia perforata anterior, in which they end.

The portion of the upper surface of the *thalamus* which appears in the floor of the lateral ventricle is, in great part, overlaid by the *chorioid plexus* of the lateral ventricle. The plexus is a rich vascular fringe which appears from under cover of the sharp edge of the fornix. It is continuous anteriorly, through the interventricular foramen, with the corresponding chorioid plexus of the opposite side; whilst

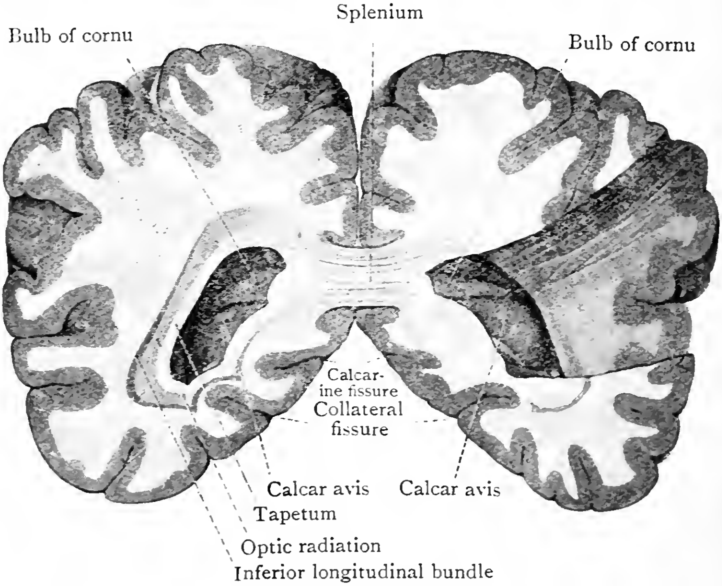

FIG. 169.—Frontal section through the Posterior Horns of the Lateral Ventricles.

posteriorly, it is carried into the inferior horn of the ventricle. Although the chorioid plexus has all the appearance of lying free within the ventricle, it is invested by an epithelial layer of ependyma, which excludes it from the cavity and is continuous on the one hand with the ependyma on the sharp margin of the fornix, and on the other with the ependyma of the upper surface of the thalamus.

Cornu Posterius Ventriculi Lateralis.—The posterior horn is a diverticulum which runs, from the posterior end of the central part of the ventricle, into the occipital lobe. It tapers to a point and describes a gentle curve, the convexity of which is directed laterally. The *roof* and the *lateral wall* of

the posterior horn are formed by the tapetum of the corpus callosum (see p. 426).

Upon the *medial wall* two elongated, curved elevations may be seen. The upper of the two is termed the *bulb of the cornu*, and is produced by the fibres of the forceps major as they curve, backwards, from the lower part of the splenium of the corpus callosum into the occipital lobe. The lower elevation is known as the *calcar avis*. It varies greatly in size, in different brains, and is caused by an infolding of the ventricular wall which corresponds with the anterior part of the calcarine fissure.

> ***Dissection.***—If the opercula have not already been removed to expose the insula, the dissector should now insinuate his fingers underneath the fronto-parietal operculum of the insula on the right side and tear that portion of the cortex away in an upward direction. The frontal operculum (pars triangularis) and the orbital operculum should be dealt with in the same manner. The greater part of the temporal operculum has already been removed in opening up the inferior horn of the ventricle; therefore the insula is now fully exposed to view, and its relation to the parts in the interior of the ventricle can be seen.

Cornu Inferius Ventriculi Lateralis (O.T. **Descending Cornu**).—The inferior horn must be regarded as the direct continuation of the main ventricular cavity into the temporal lobe. The posterior horn is merely a diverticulum from the main cavity. At first directed backwards and laterally, the inferior horn suddenly sinks downwards, posterior to the thalamus, into the temporal lobe, in which it takes a curved course, forwards and medially, to a point about 25 mm. (*one inch*) posterior to the extremity of the temporal pole. In the angle between the diverging inferior and posterior horns the cavity of the ventricle exhibits a triangular expansion of varying capacity. It is called the *trigonum collaterale*.

The *lateral wall* of the inferior horn is formed, for the most part, by the tapetum of the corpus callosum. At the extremity of the horn the *roof* presents a slight bulging into the ventricular cavity. The bulging is called the *amygdaloid tubercle*, and it is produced by a superjacent collection of grey matter, termed the *amygdaloid nucleus*. The *stria terminalis* and the greatly attenuated *tail of the caudate nucleus* are both prolonged into the inferior horn, and are carried forwards, in its roof, to the amygdaloid nucleus.

On the *floor* of the inferior horn the dissector will note the following parts: (1) the hippocampus; (2) the chorioid plexus; (3) the fimbria; and (4) the eminentia collateralis.

Hippocampus (O.T. **Hippocampus Major**).—The hippocampus is overlapped by the chorioid plexus, which must be turned aside. It is a prominent elevation in the floor of the inferior horn of the lateral ventricle, and is strongly curved in conformity with the course taken by the horn in which it lies. It presents, therefore, a concave medial margin and a convex lateral margin. Narrow posteriorly, it enlarges as it is traced forwards, and it ends, below the amygdaloid tubercle,

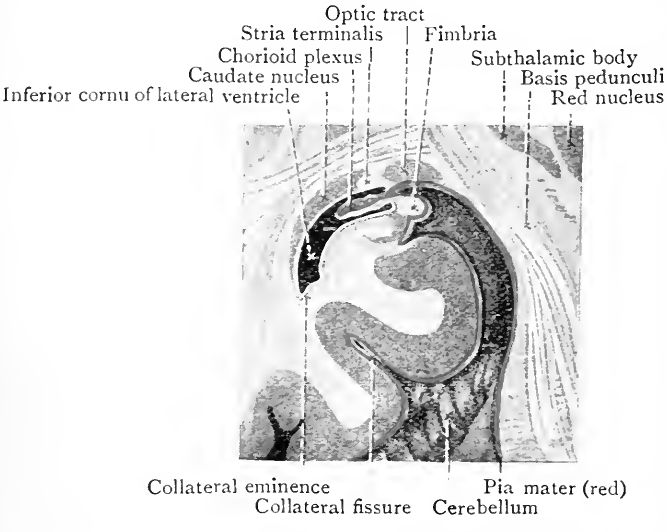

FIG. 170.—Frontal Section to show relations of Inferior Cornu of Lateral Ventricle. (Part of Fig. 188 enlarged.)

in a thickened extremity, the *pes hippocampi*. The surface of the pes hippocampi is marked by some faint grooves which intervene between a number of ridges called the *hippocampal digitations*. The hippocampal elevation is due to masses of nerve cells and the nerve fibres associated with them.

Alveus.—The alveus is a thin white layer formed by nerve fibres which arise from the cells of the hippocampus, and spread out over its ventricular surface.

Fimbria (Hippocampi).—The fimbria is a narrow but very distinct band of white matter which is attached by its lateral margin along the concave medial border of the hippocampus, immediately above the fascia dentata. The white matter com-

posing it is continuous with the thin white layer (alveus) which is spread over the surface of the hippocampus. The fimbria has two free surfaces—*superior* and *inferior*; a sharp, free *medial border*, which lies immediately above the fascia dentata, and below the chorioidal fissure; and a *lateral border*, attached to the hippocampus at its junction with the fascia dentata. It consists of the white fibres of the alveus, which assume a longitudinal direction at the margin of union of the hippocampus and the fascia dentata, and ascend to become the

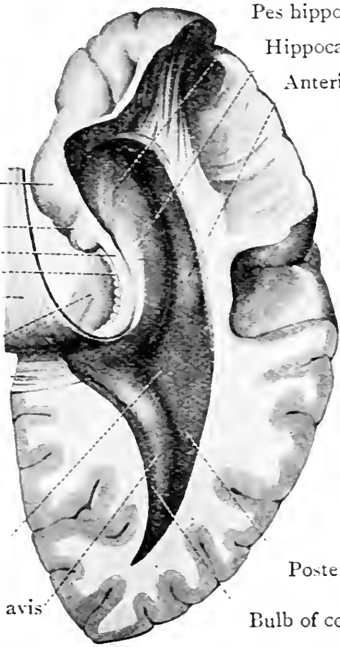

FIG. 171.—Dissection to show the Posterior and Inferior Cornua of the Lateral Ventricle.

corresponding crus of the fornix (see p. 442). It lies between the chorioid fissure and the fascia dentata (Fig. 171). Anteriorly, it runs into the recurved extremity of the uncus; and postero-superiorly, as already stated, it becomes continuous with crus of the fornix.

Chorioid Fissure of the Cerebrum.—When the pia mater in the region of the hippocampal gyrus and the fascia dentata is removed from the surface of the brain, the chorioid plexus in the interior of the inferior horn of the lateral ventricle is sometimes withdrawn with it, and a fissure then appears between the fimbria and the roof of the ventricular horn. That fissure is

part of the *chorioid fissure of the cerebrum*; and it is the lateral part of the *great transverse fissure*. By the withdrawal of the chorioid plexus it is converted into an artificial gap, which

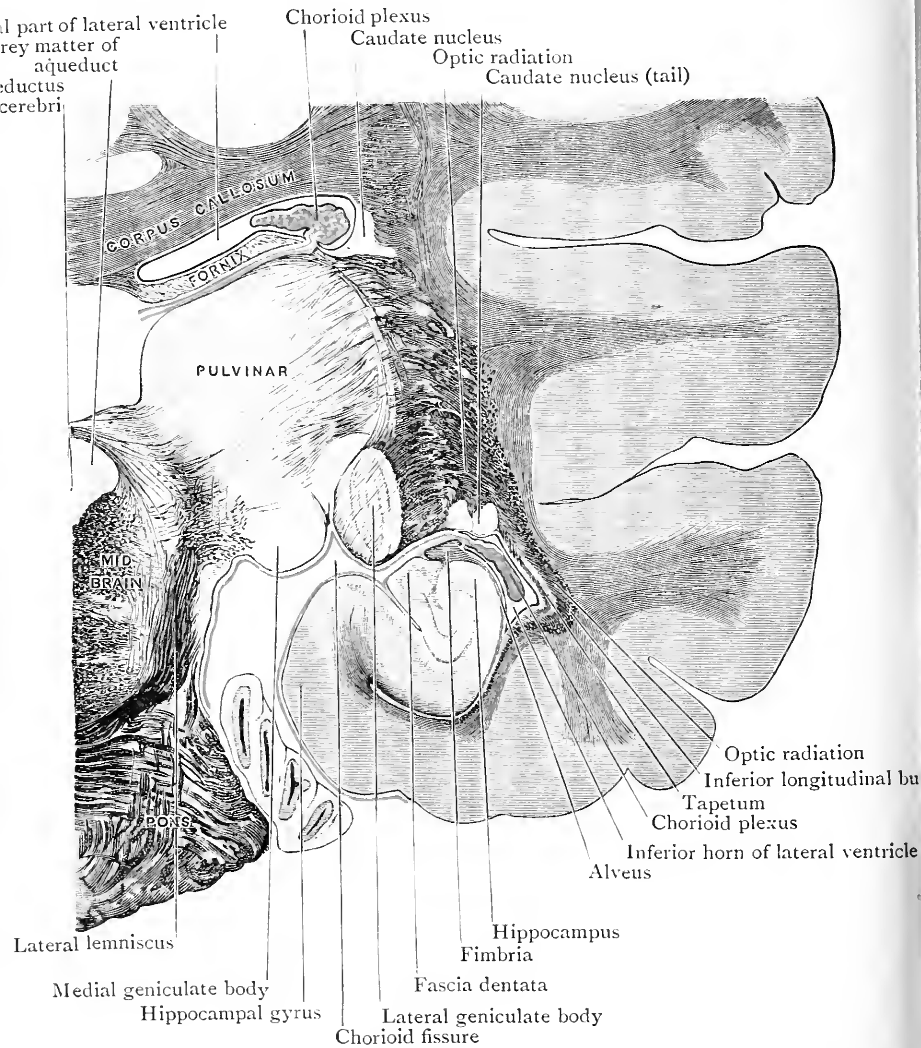

FIG. 172.—Frontal section through the Cerebrum, Mid-brain, and Pons in the plane of the geniculate bodies. It shows the relation of the chorioid fissure to the inferior horn of the lateral ventricle.

leads directly from the exterior of the brain into the interior of the inferior horn of the lateral ventricle.

Plexus Chorioideus.—The chorioid plexus is a system of convoluted blood vessels, enclosed within a fold of pia

mater, which is prolonged, into the inferior horn and the central part of the lateral ventricle, through the chorioid fissure of the cerebrum. In the inferior horn it lies on the surface of the hippocampus and, at the posterior extremity of the thalamus, it becomes continuous with the chorioid plexus in the central part of the lateral ventricle (Fig. 166). But it must not be supposed that the chorioid plexus lies free in the ventricular cavity. It is clothed in the most intimate manner by an epithelial ependymal layer, which represents part of the original medial surface of the hemisphere pushed into the cavity by the chorioid plexus. The ventricle, therefore, opens on the surface through the chorioid fissure only after the thin epithelial layer is torn away by the withdrawal of the chorioid plexus.

Eminentia Collateralis.—The collateral eminence is sometimes separated into two parts, which may be distinguished from each other as the eminentia collateralis posterior and the eminentia collateralis anterior (Figs. 166, 171).

The *posterior collateral eminence* is a smooth elevation in the floor of the trigonum collaterale, in the interval between the calcar avis and the hippocampus as they diverge from one another. The *anterior collateral eminence* is not always present. It forms an elongated elevation in the floor of the inferior horn of the lateral ventricle, to the lateral side of the hippocampus. Both eminences correspond to the collateral fissure on the inferior aspect of the cerebral hemisphere.

Dissection.—The dissector should now detach the remains of the right temporal lobe and of the right occipital lobe from the rest of the cerebrum by cutting through the forceps major of the splenium of the corpus callosum and through the fimbria where it passes into the crus of the fornix. The knife should then be carried forwards from the anterior extremity of the inferior horn, above the level of the uncus, through the temporal pole. The temporal lobe, including the hippocampal gyrus along its medial side, can then be separated from the remainder of the brain, along the line of the chorioid fissure of the cerebrum. In the detached part of the cerebrum (Fig. 171) a good view is obtained of the floor of the inferior horn and of the parts in relation to it. Further, by replacing it in position, the dissector will be better able to understand the chorioid fissure, and by turning the brain upside down he will obtain a view of the roof of the inferior horn and the structures in relation to it. In that way the tail of the caudate nucleus and the stria terminalis can be traced into the amygdaloid nucleus.

The cut edge of the central part of the corpus callosum, which

is still in position, should now be still further pared away, so as to bring the subjacent septum pellucidum and the fornix more fully into view.

Upon the portion of the temporal lobe which has been separated, the dissector should examine again the *fascia dentata*, which was mentioned on p. 414, and which is now much more accessible.

Fascia Dentata Hippocampi.—The fascia dentata is the free edge of grey matter which is placed between the fimbria and the deep part of the upper surface of the hippocampal gyrus. The groove between it and the fimbria is termed the *fimbrio-dentate sulcus*. The margin of the fascia is notched, and its surface is scored with numerous closely-placed vertical grooves. It begins posteriorly, in the region of the splenium of the corpus callosum, as the fasciola cinerea (Fig. 173), and it runs forwards into the cleft of the uncus, from which it emerges again in the form of a delicate band, called the *cauda fasciæ dentatæ*, which crosses the recurved part of the uncus in a transverse direction. The cauda is not always easily seen.

Septum Pellucidum—Fornix—Tela Chorioidea Ventriculi Tertii.

Septum Pellucidum.—The septum pellucidum is a thin vertical partition which intervenes between the anterior cornua and the anterior parts of the central portions of the two lateral ventricles (Fig. 164). It occupies the triangular interval between the corpus callosum and the body and columns of the fornix, being attached, above and anteriorly, to the corpus callosum, and below and posteriorly, to the fornix. It consists of two thin laminæ which form the side walls of a median cleft called the *cavum septi pellucidi* (Figs. 164, 174).

Dissection.—The narrow median strip of the corpus callosum, posterior to the genu, should now be removed. Cut it transversely across, and, gently raising it, separate the upper edge of the septum pellucidum from its lower surface. Posterior to the septum pellucidum the under surface of the median part of the corpus callosum will be found to lie upon and to be connected with the upper surface of the fornix. Sever that connection also. The left half of the forceps major should be preserved, so that its connection with the occipital lobe may be more fully made out later. Snip off the upper edge of the septum pellucidum with the scissors, in order to demonstrate the two laminæ with the interposed cleft.

Cavum Septi Pellucidi (O.T. **Fifth Ventricle**).—The cavity of the septum pellucidum is the name applied to the median cleft between the two laminæ of the septum. It varies greatly in extent, in different brains, and it contains a little fluid. It is completely isolated, having no communication either with the ventricles or with the exterior.

Fornix.—The fornix is an arched structure, composed of longitudinal and transverse fibres. It consists of a central part or body, which ends in two columns anteriorly and two crura posteriorly.

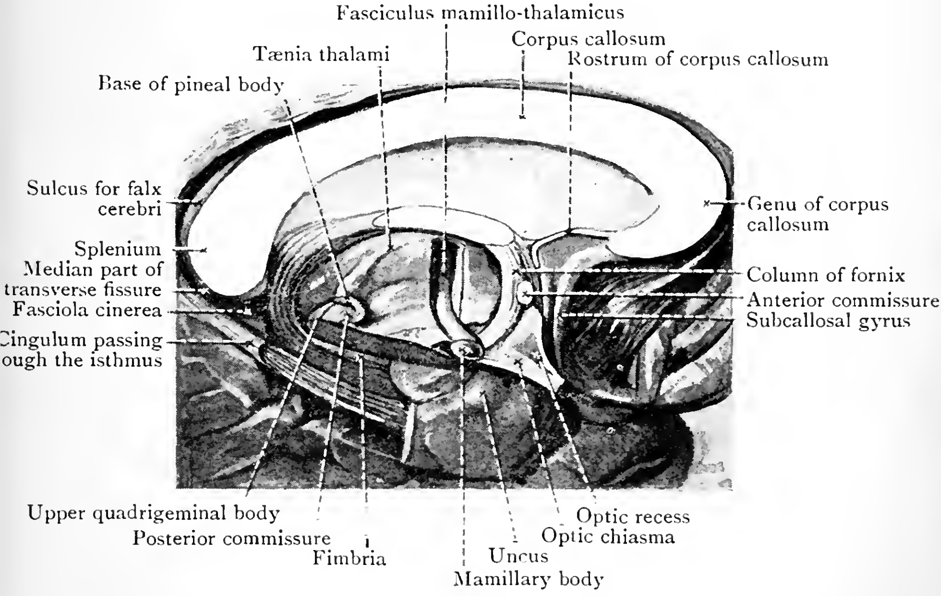

FIG. 173.—Dissection showing the relations of the Fornix.

Corpus Fornicis.—The body of the fornix is triangular in shape. Anteriorly, where it is continuous with the columns, it is narrow; posteriorly it broadens out, becomes flattened, and is prolonged into the crura (Fig. 166). The posterior part of the upper surface of the body of the fornix is in contact with and is adherent to the inferior surface of the posterior part of the body of the corpus callosum. The remaining part of the upper surface of the median portion of the fornix is attached to the posterior part of the lower edge of the septum pellucidum. Lateral to those attachments the upper surface of the body of the fornix forms a part of the floor of the lateral ventricle, on each side, and is clothed with

ependyma. Each lateral margin is a sharp edge, from under which the chorioid plexus projects into the cavity of the corresponding lateral ventricle. The lower surface of the body of the fornix rests upon the tela chorioidea of the third ventricle (O.T. velum interpositum), a fold of pia mater which separates it from the third ventricle and the two thalami (Figs. 168, 187).

Columnæ Fornicis (O.T. *Anterior Pillars*). — The two columns of the fornix are two rounded strands which emerge from the anterior end of the body of the fornix, and then, diverging slightly, pass downwards, anterior to the interventricular foramina. They then sink into the grey matter on the side walls of the third ventricle, and end at the base of the brain in the corpora mamillaria (Figs. 160, 173).

Each mamillary body has the appearance of being a twisted loop of the corresponding column of the fornix, in which the fibres turn upon themselves, and are then continued upwards and backwards into the anterior tubercle of the thalamus. The appearance, however, is deceptive. In the interior of the corpus mamillare there is a nucleus of grey matter. In that nucleus the fibres of the column end; while the other fibres, which seem to be continuous with the fornix fibres, take origin within the nucleus. The strand, thus formed, is called the fasciculus mamillo-thalamicus (O.T. bundle of Vicq d'Azyr) (Fig. 173).

The connections which have just been described cannot be made out at present, but at a later period the dissector will experience little difficulty in tracing a column of the fornix to the corresponding corpus mamillare, and in displaying the connection of corpus mamillare with the fasciculus mamillo-thalamicus.

Crura Fornicis (O.T. *Posterior Pillars*).—The crura of the fornix are flattened bands which diverge from the posterior part of the body of the fornix. At first they are adherent to the under surface of the corpus callosum, but soon they sweep downwards, round the posterior ends of the thalami, and enter the inferior horns of the lateral ventricles. There each crus comes into relation with the corresponding hippocampus, and some of its fibres spread out on the surface of that prominence, where they form the *alveus*, whilst the remainder constitute the fimbria, which has been described already (p. 436, Fig. 171).

The transverse fibres of the fornix cross the lower surface of the body and the anterior part of the interval between the diverging crura. In the latter place they may be adherent to the lower surface of the corpus callosum. On each side they are continuous with the longitudinal fibres of the crura

and so are prolonged, in the inferior horn, into the fimbria and the alveus. They constitute a transverse commissure from one hippocampus to the other.

Dissection.—The body of the fornix should now be divided transversely, across its middle. Its posterior and anterior portions may then be raised from the tela chorioidea of the third ventricle, and thrown apart from each other. Had it been possible to raise the corpus callosum and fornix together, the

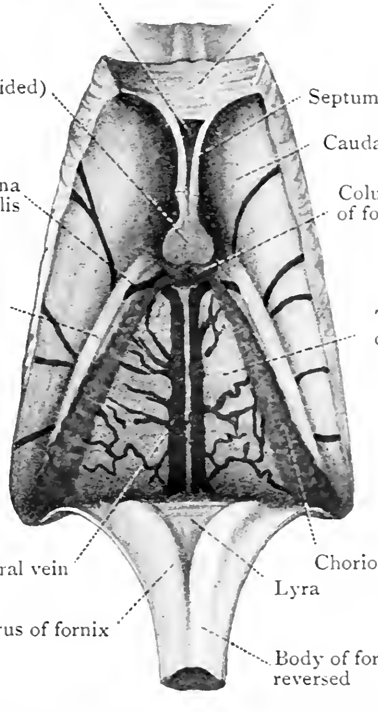

FIG. 174.—Dissection to show the Tela Chorioidea of the Third Ventricle and the parts in its vicinity. The fornix has been divided and thrown backwards.

diverging crura of the fornix would have been seen to limit a triangular space on the under surface of the corpus callosum, anterior to the posterior margin of the splenium. That interval is termed the *lyra* ; it is traversed by a series of oblique markings which indicate the presence of the transverse fibres passing across from one crus of the fornix to the other.

Tela Chorioidea Ventriculi Tertii (O.T. **Velum Interpositum**).—The tela chorioidea of the third ventricle consists of two layers of pia mater which form a fold of triangular outline. It intervenes between the body of the fornix, above, and the roof of the third ventricle and the two thalami,

below. Between the two layers are blood vessels and some subarachnoideal trabecular tissue. The narrow, anterior end of the triangular fold lies between the interventricular foramina. The base is situated under the splenium of the corpus callosum, and there the upper of the two layers of pia mater which form the tela becomes continuous with the pia mater on the corpus callosum, and the lower layer becomes continuous with the pia mater on the lamina quadrigemina (Fig. 141).

In each of the two margins of the tela lies the chorioid plexus of the central part of the corresponding lateral ventricle. The plexus projects into the ventricular cavity from under cover of the free edge of the fornix. Posteriorly, it is continuous with the part of the chorioid plexus which lies in the inferior horn of the ventricle; whilst anteriorly, it narrows greatly, and becomes continuous, across the median plane, with the corresponding plexus of the opposite side. From the median junction two much smaller chorioid plexuses run, backwards, in the lower surface of the tela, and project downwards into the third ventricle. These are the *chorioid plexuses of the third ventricle* (Fig. 175).

The most conspicuous blood vessels in the tela chorioidea of the third ventricle are the two *internal cerebral veins* (O.T. *veins of Galen*), which run backwards—one on each side of the median plane. Each internal cerebral vein is formed, at the apex of the fold, by the union of the vena terminalis with a large vein issuing from the chorioid plexus; posteriorly, they unite to form the *great cerebral vein* (O.T. *vena magna Galeni*), and that vein pours its blood into the anterior end of the straight sinus (Fig. 35).

Fissura Transversa Cerebri.—The name *transverse fissure* is given to the continuous cleft through which the tela chorioidea of the third ventricle and the chorioid plexuses of the inferior horns of the lateral ventricles are introduced into the interior of the brain. It consists of an upper or middle part and two lateral parts. The middle part lies between the splenium of the corpus callosum and the body of the fornix, above, and the mid-brain, below. The base of the tela chorioidea of the third ventricle lies in it, and the blood vessels which enter and leave the tela pass through it, between the layers of the tela.

The lateral parts of the transverse fissure are the inferior

parts of the *chorioidal fissures*, which have been studied already in connection with the inferior horn of the lateral ventricle (p. 437).

Dissection.—Each vena terminalis should now be divided as it unites with the internal cerebral vein. The apex of the tela chorioidea should then be seized with the forceps and pulled backwards, till the whole structure is reversed. As that is done, care must be taken to avoid injury to the attachments of the pineal body, which is enclosed in a fold of the posterior part of the lower layer of the tela. When the tela chorioidea has been displaced backwards to the level of the mid-brain, the entire upper surface of the thalamus on each side is exposed, and, between the thalami, the cavity of the third ventricle is seen. The epithelial roof of that ventricle, which is invaginated into the cavity by the chorioid plexuses of the third ventricle on the under surface of the tela, is torn away with the tela.

THE THALAMI AND THE THIRD VENTRICLE.

Thalamus.—The thalamus is a large mass of grey matter which lies obliquely across the path of the corresponding

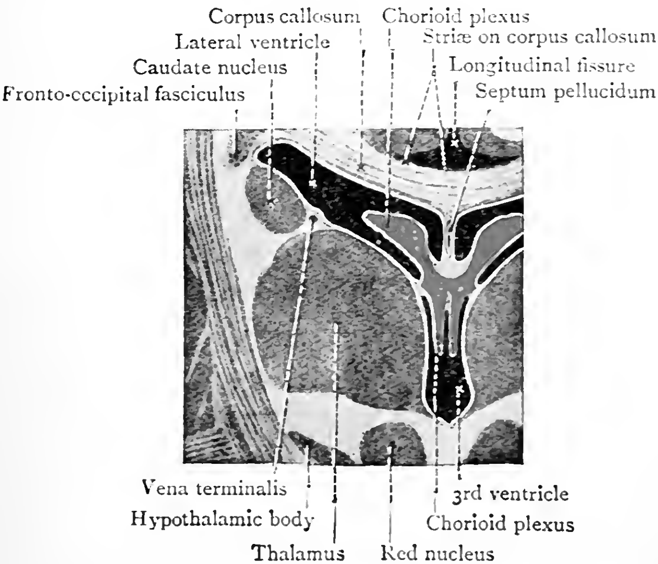

FIG. 175.—Frontal section showing immediate relations of Lateral and Third Ventricles. (Part of Fig. 188 enlarged.)

pedunculus cerebri as it ascends into the hemisphere. In their anterior two-thirds, the two thalami lie close together, but are separated by a deep median cleft called the third ventricle; the posterior thirds are further apart from one

another, and the corpora quadrigemina of the mid-brain lie between them, on a lower plane. Each thalamus presents a small anterior extremity and a large posterior extremity, and four surfaces. The inferior and lateral surfaces are in apposition with, and, indeed, directly connected with adjacent parts. The superior and medial surfaces are free.

The *lateral surface* of each thalamus is applied to a mass

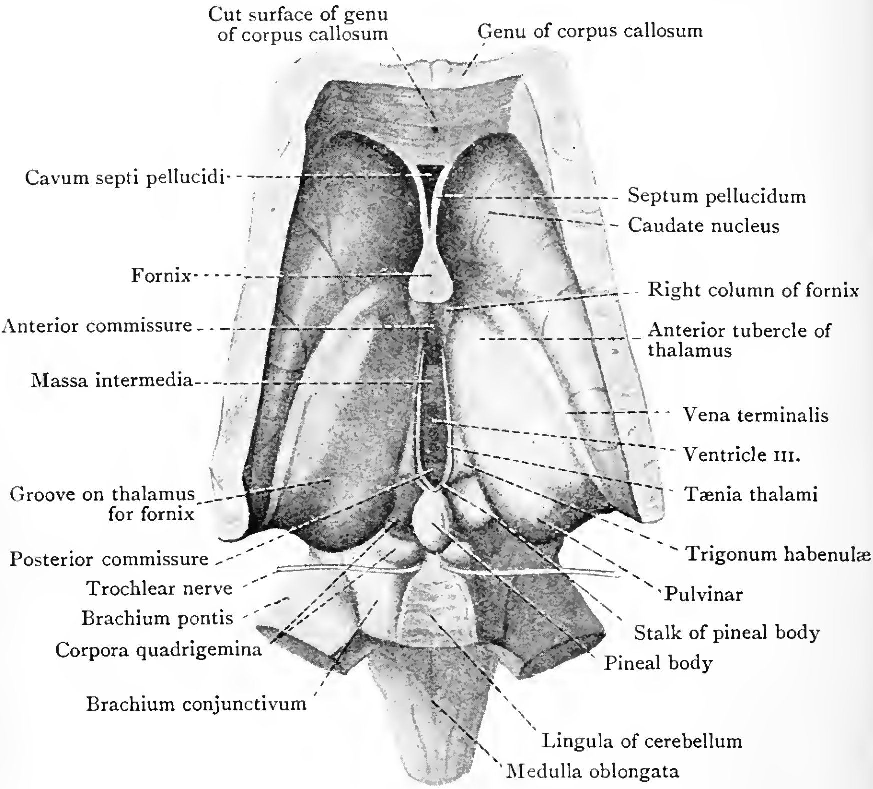

FIG. 176.—The two Thalami and the Third Ventricle as seen from above.

of white matter, termed the *internal capsule*, which is composed largely of fibres from the *basis pedunculi* of the mid-brain (Fig. 188). The *inferior* or *ventral surface* of the thalamus rests chiefly upon the *subthalamic region*, which is the prolongation upwards of the tegmental part of the pedunculus cerebri. The relation, therefore, which the thalamus presents to the upward continuation of the pedunculus cerebri is very intimate.

The *superior surface* of the thalamus is free. On the lateral side it is bounded by the groove which inter-

venes between the thalamus and the caudate nucleus and contains the vena terminalis and the stria terminalis. On the medial side, the superior surface of the thalamus is separated from the medial surface, in its anterior half, by a sharp edge, or prominent ledge, of the ependyma of the third ventricle. The ledge is called the *tænia thalami.* It is produced by a longitudinal strand of fibres, called the *stria medullaris*, which lies beneath the ependyma. A short distance anterior to the pineal body the tænia lies upon the upper border of a raised white band, called the *habenula*, which is directly continuous with the stria medullaris.

The habenula divides posteriorly into two parts, one of which becomes associated with the cells of the grey matter of the trigonum habenulæ of the same side (*see below*); the fibres of the other part pass through the roof of the third ventricle immediately in front of the upper part of the stalk of the pineal body. They go to the trigonum habenulæ of the opposite side and, together with their fellows of the opposite side, they form the *habenular commissure* (Fig. 177).

Between the habenula medially and the upper quadrigeminal body posteriorly, lies a small triangular depressed area, the *trigonum habenulæ.*

The superior surface of the thalamus is slightly convex, and is of a whitish colour owing to the presence of a thin superficial coating of nerve fibres (stratum zonale). It is divided into two areas by a faint oblique groove which begins near the anterior extremity of the thalamus, and extends obliquely, laterally and backwards. The sulcus corresponds to the free edge of the fornix. The two areas thus mapped out are very differently related to the ventricles of the brain. The *lateral area* includes the anterior extremity of the thalamus, and forms a part of the floor of the lateral ventricle; it is covered with ependyma, and overlapped by the chorioid plexus. The *medial area* intervenes between the lateral and third ventricles of the brain, and takes no part in the formation of the walls of either. It is covered with the tela chorioidea, above which is the fornix. It includes the posterior extremity of the thalamus.

The *anterior extremity* of the thalamus, called the *anterior tubercle*, is rounded and prominent. It projects into the lateral ventricle, lies postero-lateral to the corresponding column of the fornix, and forms the posterior boundary of the interventricular foramen.

The *posterior extremity* of the thalamus is very prominent, and it projects backwards over the mesencephalon (Fig. 176).

The most projecting part is called the *pulvinar*. But the posterior end of the thalamus shows another prominence, which is situated below and to the lateral side of the pulvinar. It is oval in form, and receives the name of the *corpus geniculatum laterale.*

The anterior two-thirds of the *medial surfaces* of the two thalami are placed very close together, and are covered not only with the lining ependyma of the third ventricle, but also with a moderately thick layer of grey matter continuous with the grey matter which surrounds the aquæductus cerebri (Sylvius). A band of grey matter, termed the *massa intermedia*, crosses the third ventricle and joins the two thalami together.

Corpus Pineale.—The pineal body is a small body of a darkish colour, and about the size of a cherry-stone, which is placed on the dorsal aspect of the mesencephalon between the posterior extremities of the two thalami (Figs. 176, 179). It occupies the depression between the two superior colliculi of the quadrigeminal lamina, and is shaped like a fir-cone. Its base, which is directed forwards, is attached by means of a hollow stalk or peduncle. The stalk is separated into a dorsal and a ventral part by a continuation into it of a pointed recess of the cavity of the third ventricle. The dorsal part of the stalk becomes continuous, on each thalamus, with the tænia thalami, and through it pass the fibres of the habenular commissure; the ventral part is folded round a narrow but conspicuous cord-like band of white fibres (*posterior commissure*) which crosses the median plane immediately below the base of the pineal body.

Commissura Anterior Cerebri.—In the anterior part of the cleft between the two thalami, and immediately anterior to the columns of the fornix, a round bundle of white fibres will be seen crossing the median plane (Figs. 177, 173). It is the *anterior commissure.* It is very much larger than the posterior commissure, and will be afterwards followed towards the temporal lobe, in which the greater part of it ends.

Ventriculus Tertius.—The third ventricle is the name given to the deep, narrow cleft between the two thalami. It is deeper anteriorly than posteriorly, and extends from the pineal body posteriorly to the anterior commissure and lamina terminalis anteriorly. Its *floor* is formed by the parts already studied within the interpeduncular fossa on the base of the brain, viz., the tuber cinereum, the corpora mamillaria, and

the grey matter of the substantia perforata posterior, and also, more posteriorly, by the tegmenta of the cerebral peduncles. *Anteriorly*, it is bounded by the lamina terminalis, the anterior commissure, and the columns of the fornix. At the angle of junction of the anterior boundary and the floor lies the optic

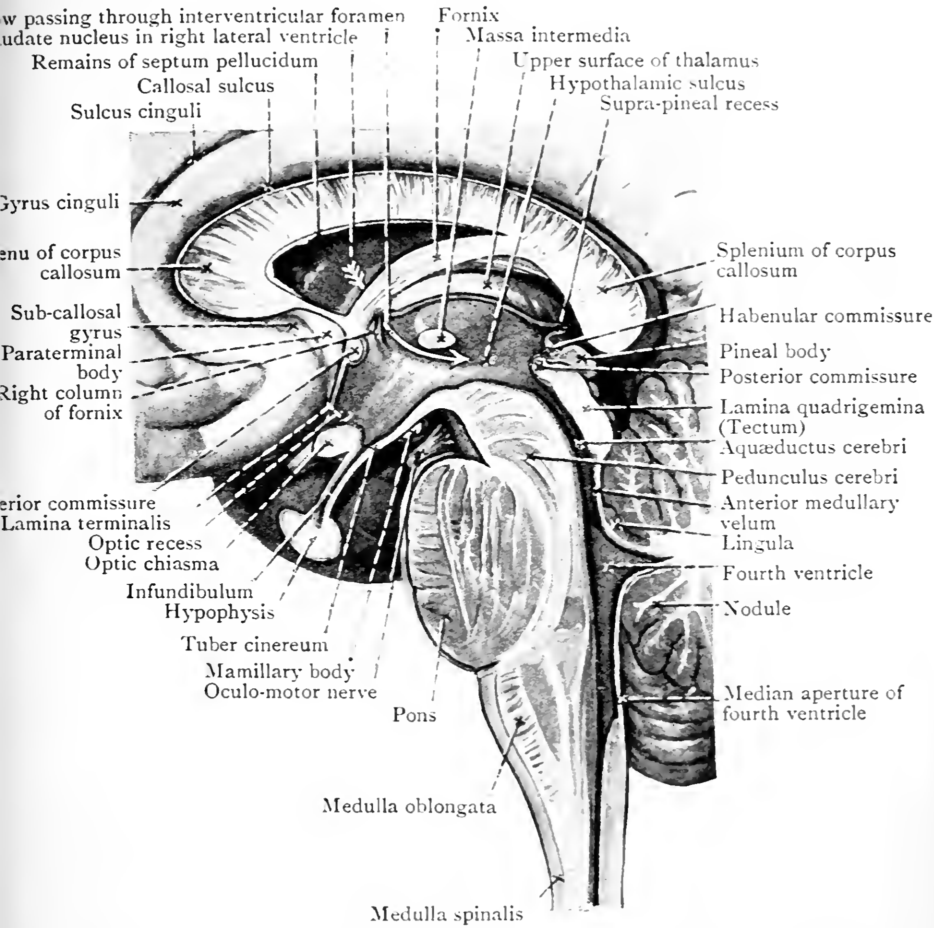

FIG. 177.—Sagittal section of Corpus Callosum, Fornix, Diencephalon, Mid-brain, and Hind-brain. The septum pellucidum has been removed to expose the cavity of the right lateral ventricle, from which an arrow passes through the interventricular foramen to the third ventricle.

chiasma. Each *side wall* is formed by the medial surfaces of the corresponding thalamic and hypothalamic parts of the diencephalon. A little anterior to the middle of the ventricle the cavity is crossed by the *massa intermedia*, which connects the thalami with each other, and anterior to that the column

of the fornix will be seen, descending in the side wall. At the anterior end of the side wall lies the interventricular foramen which is bounded in front by the corresponding column of the fornix. At the lower margin of the interventricular foramen the column of the fornix turns laterally and disappears in the anterior part of the hypothalamus to reach the mamillary body.

The *roof* of the third ventricle is formed by a thin epithelial layer which stretches across the median plane, from the one tænia thalami to the other. It is applied to the under surface of the tela chorioidea, which overlies the ventricle, and is invaginated into the cavity by the chorioid plexuses which hang down from the under surface of that fold of pia mater. In the removal of the tela chorioidea the thin epithelial roof was torn away (Figs. 175, 187).

The third ventricle communicates with the lateral ventricles, through the *interventricular foramina*, and it communicates with the fourth ventricle by the *aquæductus cerebri* (*Sylvius*), a narrow channel which tunnels the mesencephalon. The opening of this canal will be seen in the posterior wall of the third ventricle, immediately below the posterior commissure. The *interventricular foramina*, which put the third into communication with the two lateral ventricles, lie at the anterior part of the third ventricle, one on each side. Each passes laterally and slightly upwards, between the most prominent part of the corresponding column of the fornix and the anterior tubercle of the thalamus. Through the foramina the epithelial lining of the third ventricle becomes continuous with that of the lateral ventricles (Figs. 177, 165, 166).

From each interventricular foramen a distinct groove passes backwards, on the side wall of the ventricle, to the mouth of the aquæductus cerebri. It is termed the *sulcus hypothalamicus*, and it separates the ventral part of the boundary of the third ventricle, which is called the hypothalamus, from the more dorsally placed thalamus.

The outline of the third ventricle is seen to be very irregular when it is viewed from the side in a median section through the brain (Fig. 177), or as it is exhibited in a plaster cast of the ventricular system of the brain (Fig. 165). It presents several diverticula or recesses. Thus, in the anterior part of the floor there is a deep funnel-shaped recess, *recessus infundibuli*, leading down, through the tuber cinereum, into the infundibulum of the hypophysis. Another recess, *recessus opticus*, lies above the optic chiasma. Posteriorly, two additional recesses are present. One, the *recessus pinealis*,

passes backwards, above the posterior commissure and the entrance of the aquæductus cerebri, into the stalk of the pineal body. The second is placed still higher, and is carried backwards for a greater distance. Its walls are epithelial, and therefore it cannot be seen in an ordinary dissection. It is termed the *recessus suprapinealis* (Fig. 177).

Dissection.—The further study of the cerebral hemispheres should be postponed until the examination of the mid-brain or mesencephalon is completed. The membranes should be removed from the upper surface of the cerebellum, and the prominent anterior part of that organ may then be pulled backwards to expose, as far as possible, the corpora quadrigemina, *i.e.* the four rounded eminences or colliculi on the dorsal aspect of the mesencephalon. As the cerebellum is displaced backwards, care should be taken to secure and preserve the slender trochlear nerves. They wind round the lateral sides of the pedunculi cerebri, after they have issued from a lamina, called the anterior medullary velum, which lies immediately below the inferior pair of colliculi.

THE MESENCEPHALON.

The mesencephalon or mid-brain is the stalk which occupies the aperture of the tentorium cerebelli, and connects the cerebral hemispheres with the parts in the posterior cranial fossa.[1] It is about three-quarters of an inch long, and it consists of a dorsal part, the *lamina quadrigemina*, and a much larger ventral part, which is formed by the two large *pedunculi cerebri*. In the undissected brain the lamina quadrigemina is completely hidden from view by the splenium of the corpus callosum, which projects backwards over it, and also by the superimposed cerebral hemispheres. The pedunculi cerebri, however, can be seen, to some extent, at the base of the brain, where they bound the posterior part of the interpeduncular fossa. The mesencephalon is tunnelled from end to end by a narrow passage called the *aquæductus cerebri* (Sylvius). The aqueduct lies much nearer the dorsal than the ventral surface of the mid-brain, and it connects the third ventricle with the fourth ventricle.

Lamina Quadrigemina.—The dorsal surface of the lamina quadrigemina is raised into four eminences or *colliculi*, two superior and two inferior, which are called the *corpora quadrigemina.* Each colliculus is composed, for the most part,

[1] If the mesencephalon was divided, when the brain was removed, the divided parts must be fixed together with pins while the superficial characters are being studied.

of grey matter, but each has also a superficial coating of white fibres. The *superior colliculi* are larger and broader than the *inferior*, but they are not so well defined nor yet so prominent.

A longitudinal and a transverse groove separate the quadrigeminal bodies from one another. The *longitudinal groove* occupies the median plane, and extends upwards as far as the posterior commissure. From its lower end a short but well-defined narrow band of white fibres, called the *frenulum veli*, passes to the anterior medullary velum, a lamina which lies immediately below the inferior pair of quadrigeminal prominences, in the roof of the fourth ventricle. The upper part of the longitudinal groove is occupied by the pineal body. The *transverse groove* curves round below each of the two superior colliculi and separates them from the inferior pair.

Brachia of the Corpora Quadrigemina.—The corpora quadrigemina form the dorsal part of the mid-brain, but each body is connected also with the corresponding lateral aspect of the mesencephalon by a prominent white strand, which is prolonged upwards and forwards under the projecting pulvinar. The strands are called the *brachia* of the corpora quadrigemina, and they are separated from each other by a continuation, on the side of the mesencephalon, of the transverse groove which separates the superior colliculi from the inferior.

Corpus Geniculatum Mediale.—Closely connected with the brachium of the inferior quadrigeminate body will be seen the medial geniculate body. It is a little oval eminence, very sharply defined, which lies on the side of the upper part of the mesencephalon under shelter of the pulvinar of the thalamus.

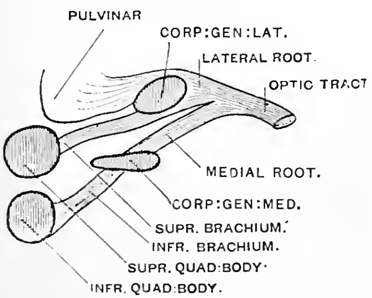

FIG. 178.—Diagram of the Roots of the Optic Tract.

Connections of the Brachia and the Termination of the Optic Tract.—There are two superior and two inferior brachia, right and left, connected respectively with the corresponding superior and inferior colliculi, and two optic tracts, right and left, which pass backwards from the optic chiasma at the base of the brain.

Each *inferior brachium* runs upwards and forwards from the

corresponding inferior colliculus and disappears from view, under cover of the medial geniculate body. Many of the fibres of which it is composed pass upwards towards the higher parts of the brain in the tegmental portion of the corresponding pedunculus cerebri, but some terminate amidst the cells of the medial geniculate body.

Each *superior brachium* passes from the side of the corresponding superior colliculus upwards, forwards, and laterally between the medial geniculate body and the pulvinar. A superficial examination of it is sufficient to show that it is connected with the lateral root of the optic tract of the same side by fibres which pass through the interval between the two geniculate bodies; and with the corresponding lateral geniculate body. It is important to remember, however, that the fibres of which it is formed are connected with other regions in addition to those indicated by superficial appearances. By means of the fibres which it receives from the optic tract it connects the superior colliculus with the retinæ of both sides. Other fibres of the superior brachium connect the superior colliculus with the lateral geniculate body; and a third series of fibres passes through the superior brachium on its way from the visual region of the occipital part of the cortex to the superior colliculus.

Tractus Optici.—The optic tracts are two relatively broad white strands, right and left, which issue from the corresponding postero-lateral angles of the optic chiasma. Each tract consists of fibres derived from the corresponding parts of the retinæ of the two sides and of fibres which connect the inferior colliculus of one side with the medial geniculate body of the opposite side. After it issues from the chiasma the tract runs backwards, first round the side of the tuber cinereum and then round the lateral side of the pedunculus cerebri, and, whilst at the side of the pedunculus cerebri, it is in relation, laterally, with the hippocampal gyrus of the cerebrum. When the tract reaches the dorsal part of the lateral aspect of the pedunculus it divides into two portions, which are called its medial and lateral roots.

The *medial root* ends in the medial geniculate body and it consists largely, if not entirely, of fibres which connect the medial geniculate body of one side with the inferior colliculus of the opposite side, and which are known as Gudden's commissure.

The *lateral root* of the optic tract consists of fibres derived from the retinæ of both sides. They terminate partly in the lateral geniculate body; partly in the pulvinar; and partly in the superior colliculus of the same side, to which they pass through the superior brachium.

Pedunculi Cerebri (O.T. **crura cerebri**).—The cerebral peduncles constitute the chief bulk of the mesencephalon. When the brain is viewed from below, they appear as two large rope-like strands, which emerge, close together, from the upper aspect of the pons, and diverge as they proceed upwards and forwards to the cerebral hemispheres At the

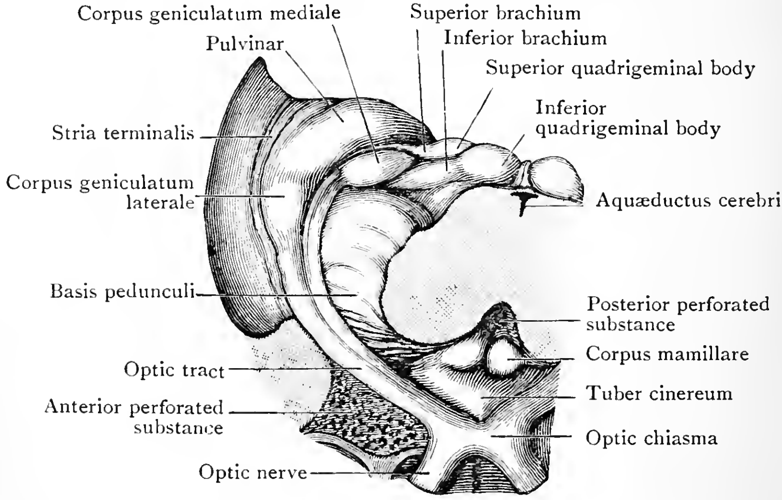

FIG. 179.—The Origin and Relations of the Optic Tract. (Professor Thane, from *Quain's Anatomy*.)

point where each peduncle disappears into the corresponding hemisphere, it is embraced, on its lateral side, by the optic tract and the gyrus hippocampi.

Each pedunculus cerebri consists of two parts, viz., a dorsal part, called the *tegmentum*, which is prolonged upwards to the region below the thalamus; and a ventral part, called the *basis* (O.T. *crusta*), which is carried upwards into a layer of white fibres called the internal capsule, situated on the lateral side of the thalamus. When the brain is examined from below the bases of the peduncles are seen. They are white in colour and streaked in the longitudinal direction. On the exterior of the mesencephalon, the separation between the two parts of the pedunculus cerebri (*i.e.* the tegmentum

and the basis pedunculi) is indicated by a medial and a lateral groove or sulcus. The medial sulcus is the deeper and more distinct. It looks into the interpeduncular fossa, and from it emerge the fila of the oculo-motor nerve. It consequently receives the name of the *sulcus oculomotorius*. The lateral groove is termed the *sulcus lateralis*.

Cut Surface of the Mesencephalon. — When the cut surface of a mesencephalon, which has been divided transversely, is examined, the first point which should be noted is the position of the *aquæductus cerebri* (Figs. 180, 181). It is a narrow passage which lies nearer the dorsal surface than the ventral surface of the mesencephalon, and it leads from the fourth ventricle, below, to the third ventricle, above. It is surrounded by a thick layer of grey matter, called the *central grey matter of the aqueduct*. In a fresh brain the central grey matter is always very conspicuous, and in its midst are situated the nuclei of the oculo-motor and trochlear nerves, and the upper nucleus of the trigeminal nerve, but, except in very favourable circumstances, the positions of the nuclei cannot be detected by the naked eye. The grey matter of the aqueduct is continuous, below, with the grey matter spread out on the anterior wall of the fourth ventricle; whilst, above, it is continuous with the grey matter on the floor and sides of the third ventricle.

The division between the tegmentum and the basis pedunculi, on each side, is rendered very evident by a conspicuous lamina of dark pigmented matter, termed the *substantia nigra*, which intervenes between them.

Substantia Nigra.—As seen in transverse section, the substantia nigra presents a somewhat crescentic outline. It is a thick band interposed between the basal and tegmental parts of each pedunculus cerebri, and it consists of grey matter many of the cells of which are deeply pigmented. It begins, below, at the upper border of the pons, and it extends upwards into the subthalamic region. Its margins come to the surface at the oculo-motor and lateral sulci, and its medial part is traversed by the merging fibres of the oculo-motor nerve. The surface turned towards the tegmentum is concave and uniform; the opposite surface is convex, and is rendered highly irregular by the presence of numerous slender prolongations of its substance into the basis pedunculi.

Basis Pedunculi (O.T. **crusta**).—The basis pedunculi is somewhat crescentic when seen in section, and stands quite apart from its fellow of the opposite side. It is composed of a compact mass of longitudinally directed nerve fibres which are carried upwards into the internal capsule. The intermediate three-fifths of each basis pedunculi is formed, almost entirely, by the important *cerebro-spinal fasciculus* (O.T. *pyra-*

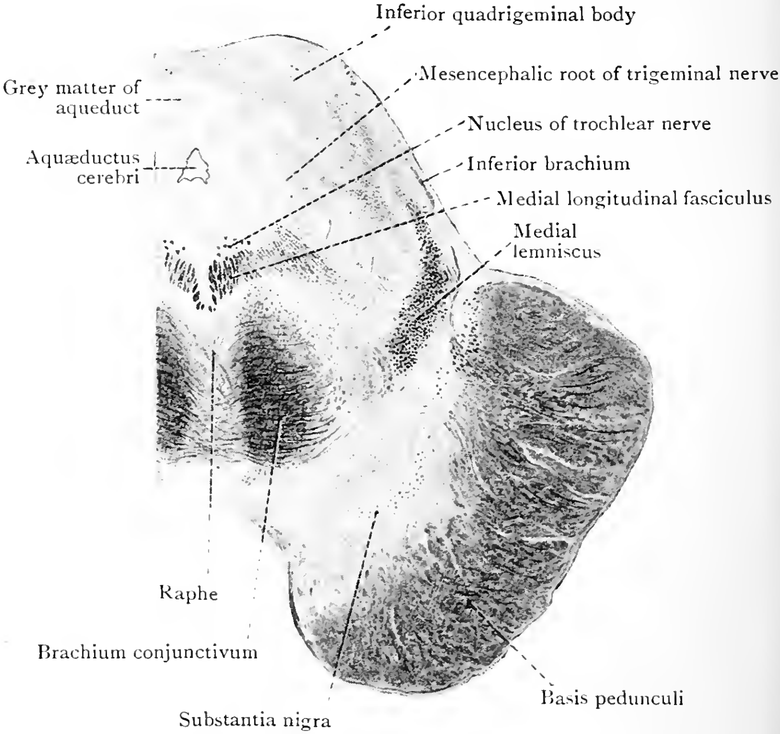

FIG. 180.—Transverse section through the Mesencephalon at the level of the inferior quadrigeminal body: the right side only is reproduced. The drawing is taken from a Weigert-Pal specimen, and therefore the grey matter is pale and the strands of white matter are dark. The dark colour of the substantia nigra is not evident owing to the thinness of the section.

midal tract) as it descends from the motor area of the cerebral cortex, but the cerebro-spinal fasciculus is quite indistinguishable, under ordinary circumstances, from the fronto-pontine fibres on its medial side and the temporo-pontine fibres on its lateral side.

Tegmentum.—Unlike the bases pedunculi, the tegmentum is undivided, a faint line in the median plane, termed the *median raphe*, alone indicating that it consists of a right and

a left half. Towards the dorsum of the mesencephalon it is fused with the deep surface of the lamina quadrigemina, and only its lateral surfaces are free.

The tegmentum is composed of an admixture of grey and white matter, constituting what is termed a *formatio reticularis.* The white matter consists of fibres running both transversely and longitudinally. Certain of the longitudinal fibres are grouped together and form well-marked tracts, which, in a section through the mesencephalon of a fresh brain, can be detected by the naked eye. The tracts are: (1) the medial longitudinal bundles; (2) the brachia conjunctiva; (3) the lemnisci.

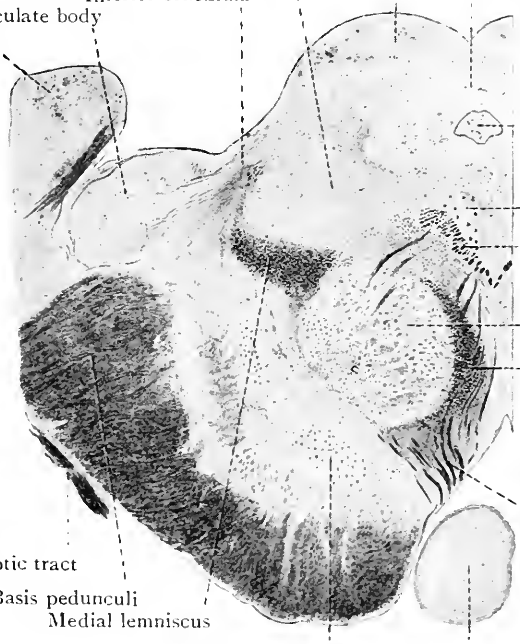

FIG. 181.—Section through upper part of Mesencephalon at level of superior quadrigeminal body. The drawing is taken from a Weigert-Pal specimen. The dark colour of the substantia nigra is not evident owing to the thinness of the section.

Fasciculus Longitudinalis Medialis.—The medial longitudinal fasciculus (Figs. 180 and 181) is a small, compact bundle which is placed upon the corresponding lateral aspect of the ventral portion of the central grey matter of the aqueduct.

The *brachia conjunctiva* (O.T. *superior cerebellar peduncles*) are two large strands which are continued upwards from the cerebellum into the mesencephalon. By pulling away the margin of the cerebellum, where it overlaps the inferior colliculi of the quadrigeminal lamina, the dissector will see the brachia on the surface as they converge in an upward direction.

Stretching across the interval between them, and bringing them into continuity with one another, is a thin lamina called the anterior medullary velum. When the brachia conjunctiva reach the bases of the inferior quadrigeminal bodies, they sink into the substance of the mesencephalon, and, in a transverse section through the lower part of that portion of the brain, they may be seen as two white strands, semilunar in outline and placed one on each side of the grey matter of the aqueduct. As they ascend, they gradually assume a deeper (*i.e.* a more ventral) position in the tegmental part of the mesencephalon, and they decussate with each other across the median plane and proceed upwards to the red nuclei.

The term *lemniscus* (O.T. *fillet*) is given to two tracts which have different connections. The *medial lemniscus* (Figs. 180 and 181) is a sensory tract passing upwards to the thalamus. The *lateral lemniscus* belongs to the acoustic apparatus, and is a part of a chain through which the cochlear nuclei of one side establish connection with the inferior quadrigeminal body and the medial geniculate body of the opposite side. The lateral lemniscus can be readily detected as it emerges from the upper part of the lateral sulcus of the mid-brain, and passes, backwards and upwards, to the lower border of the inferior quadrigeminate body and inferior brachium. It has the form of a raised triangular band which encircles the lateral surface of the upper end of the brachium conjunctivum (Fig. 194).

Within the upper part of the tegmentum there is a collection of nuclear matter which is termed the *nucleus ruber*, from its ruddy appearance when seen in section. It is rod-like in form, and extends upwards into the tegmental region below the thalamus (Fig. 188). In transverse section it presents a circular outline, and it is closely associated with the upward prolongations of the majority of the fibres of the brachium conjunctivum of the opposite side. The brachium conjunctivum cerebelli is an efferent tract from the nucleus dentatus of the hemisphere of the cerebellum, and its fibres end in the red nucleus and the pulvinar of the thalamus of the opposite side. The tegmentum of each pedunculus cerebri may be considered to consist of two parts : viz., a *lower part*, which is subjacent to the inferior quadrigeminal bodies, and is largely occupied by the decussation of the brachia conjunctiva cerebelli ; and an *upper part*, subjacent to the superior quadrigeminal bodies, which is traversed by the emerging bundles of the third nerve, and contains the nucleus ruber.

BASAL GANGLIA OF THE CEREBRAL HEMISPHERES.

The basal ganglia of the cerebral hemispheres must now be examined. They are (1) the caudate and lentiform nuclei, which, together, form the corpus striatum, (2) the claustrum, and (3) the amygdaloid nucleus. At the same time the composition of the thalamus and the external and internal capsules should be studied.

***Dissection.*—The right and left portions of what remains of the cerebrum must be separated from one another, if that has not already been done, by a median sagittal incision. Anteriorly, the incision must pass between the columns of the fornix, and**

it will divide the anterior part of the corpus callosum, the lamina terminalis, the anterior commissure and the optic chiasma. In the interval between the columns of the fornix and the corpus callosum the knife should pass through the cavity between the layers of the septum pellucidum. Posteriorly, the incision will bisect the pineal body and its peduncle, and the upper part of the lamina quadrigemina, which is still attached to the cerebrum; then it will pass through the upper part of the aquæductus cerebri,

FIG. 182.—Horizontal section through the Right Cerebral Hemisphere at the level of the widest part of the lentiform nucleus.

and, ventral to the aqueduct, it will separate the cerebral peduncles of opposite sides from one another. As the knife passes through the base of the brain, that is, through the floor of the third ventricle, from before backwards, it will divide the tuber cinereum; then it will pass between the mamillary bodies, and, posteriorly, it will bisect the posterior perforated substance. The massa intermedia, which unites the adjacent surfaces of the thalami, will be divided as the knife passes through the cavity of the third ventricle. After the division has been made the dissector should note the positions and relations of the

divided parts, and he should compare the cut surfaces with Figs. 177, 159.

When the study of the cut surfaces is completed, a horizontal incision must be made through the remains of the right half of the cerebrum, at the level of the upper part of the interventricular foramen, in order to display the relative positions of the basal ganglia. And through the left part of the cerebrum a number of frontal or vertical transverse incisions must be made, the first, immediately in front of the posterior end of the olfactory tract, the second, through the anterior perforated substance; the third, immediately anterior to the mamillary bodies, and the fourth, through the cerebrum and then through the front part of that portion of the cerebral peduncle which is still attached to it.

After the sections have been made, examine the horizontal section first (Figs. 182, 183), and note the following points, using the upper surface of the lower segment:—(1) The peripheral grey and the central white matter of the hemisphere. (2) Close to the median plane, from before backwards—(*a*) the divided anterior part of the corpus callosum and the fibres of the forceps minor passing forwards and laterally from it into the white matter of the frontal lobe; (*b*) the right layer of the septum pellucidum; (*c*) the divided right column of the fornix; (*d*) the medial surface of the thalamus, separated from the column of the fornix by the interventricular foramen; (*e*) medial to the posterior part of the thalamus, the upper surface of the anterior part of the lamina quadrigemina and a part of the pineal body. (3) Lateral to the anterior divided part of the corpus callosum is the cavity of the anterior horn of the lateral ventricle. (4) In the lateral wall of the floor of the anterior horn the divided head of the caudate nucleus of the corpus striatum. (5) Bounded medially by the head of the caudate nucleus and the thalamus, a broad band of the white matter called the *internal capsule.* (6) Lateral to the internal capsule, a triangular mass of grey matter called the *lentiform nucleus.* It is divided into three parts by two thin white laminæ called the medial and lateral medullary laminæ. The most lateral of the three parts is called the *putamen*; it is larger and darker than the medial two portions, which form, together, the *globus pallidus*, which is paler than the putamen. (7) Lateral to the lentiform nucleus, a thin lamina of white matter called the *external capsule.* It is continuous, anteriorly and posteriorly, round the anterior and posterior margins of the lentiform nucleus, with the anterior and posterior borders of the internal capsule, and it is bounded,

laterally, by—(8) A thin lamina of grey matter called the *claustrum*, which has a smooth medial surface and a scalloped lateral surface. (9) The insula, which lies lateral to the claustrum and consists of a layer of white and a layer of grey matter. It forms the medial wall of—(10) A space called the lateral fossa of the hemisphere. The lateral fossa is

FIG. 183.—Horizontal section of Corpus Striatum and adjacent parts on the right side, after the dissection represented in Fig. 182 had been made. The line to the anterior horn of the lateral ventricle crosses the right lamina of the septum pellucidum.

bounded on the lateral side by—(11) The frontal operculum, anteriorly, and (12) the temporal operculum, posteriorly, and it opens to the exterior by—(13) The lateral fissure which passes between the two opercula. (14) At the postero-lateral angle of the thalamus, note a small grey mass (see Fig. 182); it is the tail of the caudate nucleus, descending into the roof of the inferior horn of the lateral ventricle. Place the upper

segment of the divided brain on the lower segment, and trace the continuity of the caudate nucleus, along the floor of the central part of the lateral ventricle, from the divided tail, posteriorly, to the divided head, anteriorly. Then turn the lower segment of the section upside down and trace the tail of the caudate nucleus, along the roof of the inferior horn of the lateral ventricle, to the amygdaloid tubercle at the anterior end of the roof. (15) Immediately to the medial side of the divided tail of the caudate nucleus is the thin

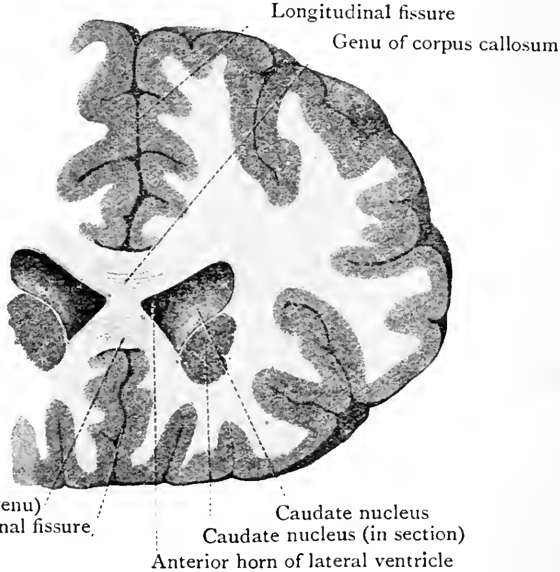

FIG. 184.—Frontal section through the Frontal Lobes of the Cerebrum. The posterior surface of the anterior part of the cerebrum is depicted so that the reader is looking into the anterior horns of the lateral ventricles from behind.

strand of white fibres, called the stria terminalis, which was noted previously in the floor of the central part of the lateral ventricle (see p. 431). Trace it also along the roof of the inferior horn to the amygdaloid tubercle.

Examine next the series of vertical transverse sections and note—(1) That, in the first section, which passes through the posterior part of the frontal lobe, the head of the caudate nucleus and the anterior part of the lentiform nucleus are fusing together, ventro-lateral to the anterior horn of the lateral ventricle (see Fig. 185). Note also that, as they blend, a striate appearance is produced by the intermingling

of a large number of grey and white striæ which pass between the two grey masses. It is because of the union and because of the striate appearance in the region of the union that the caudate nucleus and the lentiform nucleus are spoken of, together, as the corpus striatum. (2) That, in the second section, which passes through the region of the anterior perforated substance (Fig. 186), the lower surface of the

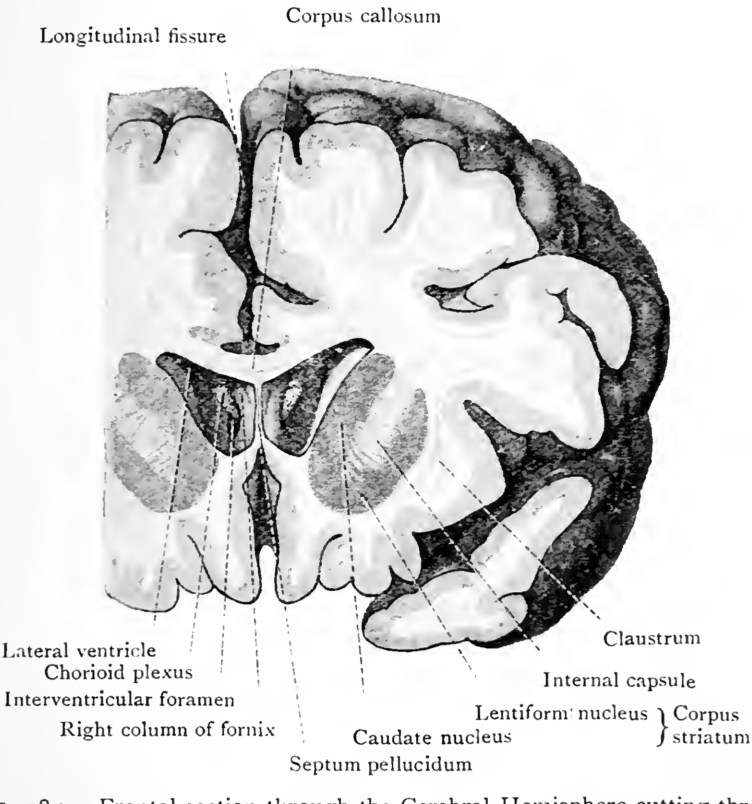

FIG. 185.—Frontal section through the Cerebral Hemisphere cutting through the anterior part of the lentiform nucleus. Seen from the anterior end.

anterior parts of the lentiform and caudate nuclei are blending with the anterior perforated substance. (3) That, in the third section, which passes between the tuber cinereum and the mamillary bodies, the main features referred to in the account of the horizontal section are again visible, but that there are some modifications due to the different plane of section (Fig. 187). The points of difference to be noted are—(*a*) That the caudate nucleus, the stria terminalis and the lateral part of the upper surface of the thalamus lie, in this section, in the

floor of the central part of the lateral ventricle. (*b*) That in the substance of the thalamus two divided white bundles are seen. The lower of the two bundles is the divided column of the fornix on its way to the mamillary body; and the higher is the fasciculus mamillo-thalamicus on its way from the mamillary body to the upper and anterior part of the thalamus. (*c*) That, lateral to the thalamus is the lentiform nucleus, clearly divided in this position into three parts by the two medullary laminæ. (*d*) That, between the lentiform nucleus, laterally, and the thalamus and the caudate nucleus, medially, is the internal capsule. (*e*) That, as the internal capsule passes

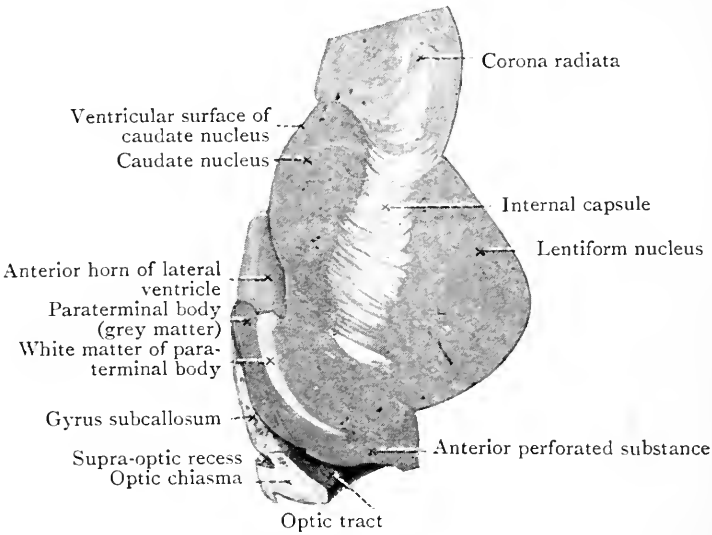

FIG. 186.—Frontal section through anterior Perforated Substance and the anterior part of Corpus Striatum, after the dissection represented in Fig. 183 had been made on the left hemisphere.

between the caudate nucleus and the upper part of the lentiform nucleus, its fibres begin to diverge towards all the adjacent parts of the cortex, forming the *corona radiata.* (*f*) That the lower end of the internal capsule is continuous with the upper and most anterior part of the pedunculus cerebri. (*g*) That, from the pedunculus cerebri fibres are passing laterally, below the lentiform nucleus, to the medullary striæ and the external capsule. (*h*) That, immediately below and lateral to the section of the pedunculus is the divided optic tract. (*i*) That, lateral to the lentiform nucleus is the external capsule, and still more laterally lie the claustrum and the insula.

Note further, that the plane of the section under consideration is anterior to the anterior end of the inferior cornu of the lateral ventricle (see Fig. 187). (4) That in the fourth section—(*a*) The fibres of the internal capsule are directly continuous, below, with the fibres of the basal or anterior part of the peduncle of the cerebrum, and, above, with the corona radiata, to which fibres converge from the adjacent parts of the grey matter of the cortex. (*b*) In the region

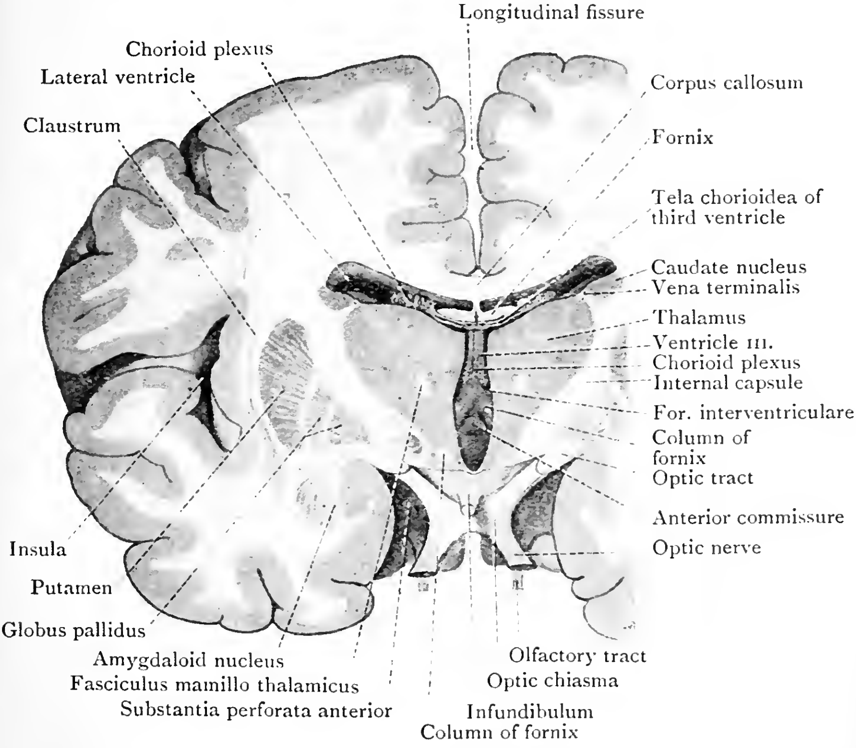

FIG. 187.—Frontal section through the Cerebral Hemisphere in such a plane as to cut the three parts of the lentiform nucleus; the posterior cut surface of the anterior part of the hemisphere is depicted.

now under consideration, the thalamus rests upon the subthalamic region which is directly continuous with the tegmental or dorsal part of the corresponding pedunculus cerebri. (*c*) In the subthalamic region two additional nodules of grey matter are easily recognisable. The medial and more rounded of the two is the upper part of the *red nucleus*, which extends downwards, through the upper half of the tegmental portion of the mid-brain. The more lateral is the

hypothalamic body, which is limited to the posterior part of the subthalamic region. (*d*) The lentiform nucleus now lies above the roof of the inferior horn of the lateral ventricle, from which it is separated by a layer of transversely directed white fibres (Fig. 188). (*e*) The lentiform nucleus is not

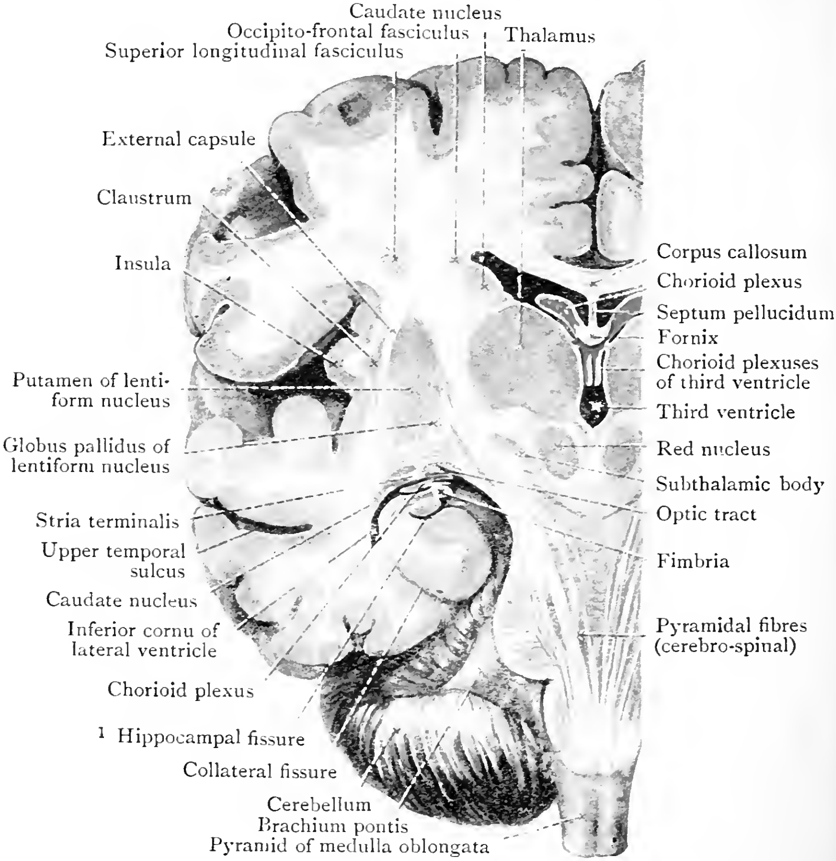

FIG. 188.—Oblique frontal section of Brain to show the course of the cerebro-spinal fibres. The internal capsule lies between the lentiform nucleus laterally and the caudate nucleus and thalamus medially.

now so distinctly divided into three segments by the medullary laminæ.

When the examination of the surface appearances of the sections is completed the dissector should study, in more detail, the parts which he has seen in various portions of their extent in the series of sections. He should replace the

[1] This fissure is an artifact (Elliot Smith).

sections in their proper relations to each other at one time, and separate them from each other again, when necessary, and so confirm the majority of the statements contained in the following accounts of the individual structures.

Corpus Striatum.—The corpus striatum is a mass of grey matter embedded in the base of the hemisphere. It consists of two parts—a supero-medial part, the caudate nucleus, and an infero-lateral part, the lentiform nucleus. The anterior portions of the two nuclei are blended together, but the remaining portions are separated from one another by a thick layer of white substance of the hemisphere, called the internal capsule.

Nucleus Caudatus.—The caudate nucleus is a comma-shaped mass. The head of the comma lies in the lateral wall of the anterior horn of the lateral ventricle. The body runs backwards, in the lateral part of the floor of the central portion of the cavity of the lateral ventricle and the tail turns downwards and forwards in the roof of the inferior horn. The lower and anterior part of the head is fused with the anterior part of the lentiform nucleus (Fig. 185). One surface of the caudate nucleus is intraventricular, that is, it is in direct relation with the cavity of the lateral ventricle and is covered with the ependyma. The opposite surface is extra-ventricular. The extraventricular surface of that part of the nucleus which lies in the anterior horn, and in the central part of the lateral ventricle, is in relation with the internal capsule, but the extraventricular surface of the portion of the tail which lies in the roof of the inferior horn of the ventricle is separated from the lower surface of the lentiform nucleus by fibres passing, more or less transversely, between the cortex of the temporal lobe and the upper part of the corresponding peduncle of the brain and the subthalamic region. The medial border of the caudate nucleus is separated from the thalamus by the stria terminalis; and the lateral border, in the region of the anterior horn and the central part of the lateral ventricle, is in relation with the medial surface of the upper part of the internal capsule, and with a bundle of longitudinal fibres of the white matter of the cerebrum called the occipito-frontal fasciculus (Fig. 188).

Nucleus Lentiformis.—The lentiform nucleus is an irregular triangular pyramid of grey matter. It possesses an inferior surface or base (Figs. 187, 188); a lateral surface;

and an antero-medial and a postero-medial surface (Figs. 182, 191).

The posterior part of the inferior surface lies above the inferior horn of the lateral ventricle, from which it is separated by some white matter and by the tail of the caudate nucleus and the stria terminalis (Fig. 188). More anteriorly the inferior surface rests upon the white matter of the temporal lobe of the hemisphere, and still more anteriorly it fuses with the grey matter of the anterior perforated substance (Fig. 186). Curving backwards and laterally in a groove on the lower surface of the lentiform nucleus lies the twisted bundle of fibres of the anterior commissure, on its way to the temporal lobe (Fig. 189).

The lateral surface is convex and is in relation, in the whole of its extent, with a layer of white matter, called the external capsule, which separates it from the claustrum.

The antero-medial and the postero-medial surfaces are in relation with the internal capsule, and the medial angle which separates the two surfaces lies in a bend of the capsule which is called the *genu* (Figs. 182, 191).

Passing vertically through the lentiform nucleus and dividing it into three parts are two white layers called the medullary laminæ. As already stated, the medial two parts are lighter in colour than the lateral part; they constitute the *globus pallidus*. The lateral part is the *putamen*.

The antero-inferior part of the lentiform nucleus is continuous with the head of the caudate nucleus and the anterior perforated substance (Fig. 186), but in the remainder of its extent the lentiform nucleus is surrounded by the white matter of the hemisphere.

The lentiform nucleus is associated with the cortex of the hemisphere, with the thalamus, and with other adjacent parts, by white nerve fibres which pass to and from the nucleus.

Claustrum.—The claustrum is a thin plate of grey matter which lies between the external capsule and the white matter of the insula. Its medial surface, which is relatively smooth, is separated from the lateral surface of the lentiform nucleus by the external capsule. Its lateral surface is scalloped, the elevations and depressions corresponding with the gyri and sulci of the insula. Its lower border, which is its broadest part, is fused, anteriorly, with the anterior perforated substance

and the amygdaloid nucleus. In extent the claustrum corresponds closely with the length and height of the insula.

Nucleus Amygdalæ.—The amygdaloid nucleus lies partly in the anterior wall of the anterior end of the inferior horn of the lateral ventricle and partly in the adjacent portion of the roof of the inferior horn. It is continuous with the tail of the caudate nucleus; with the antero-inferior part of the putamen of the lentiform nucleus; with the anterior perforated substance, and with the grey matter of the piriform area of the hippocampal gyrus.

Nuclei of the Thalamus.—When sections of the thalamus are examined it will be noticed that it is surrounded, except on its medial surface, by white matter.

The thin layer of white matter on the superior surface is termed the *stratum zonale.* It consists of fibres derived partly from the optic tract and partly from the optic radiation of the internal capsule. The white lamina on the lateral surface, which separates the grey matter from the internal capsule, is the *external medullary lamina.* The lower surface rests, anteriorly, on the hypothalamus and the temporal peduncle of the thalamus (p. 470) and posteriorly on the upper part of the tegmentum of the cerebral peduncle.

The grey matter of the thalamus is divided into three portions or nuclei by the internal medullary lamina, which consists of a posterior stem and two anterior branches. The portion of the thalamus which lies between the two branches of the internal medullary lamina is the *anterior nucleus.* It is connected with the mamillary body of the same side by the fasciculus mamillo-thalamicus. The part of the thalamus lateral to the stem and the lateral branch of the internal medullary lamina is the lateral nucleus. It is longer than the medial nucleus and includes the whole of the posterior end of the thalamus. The remaining part of the thalamus is the medial nucleus; it lies between the internal medullary lamina and the grey matter of wall of the third ventricle, but extends, backwards, only as far as the trigonum habenulæ.

The thalamus is connected with the cortex of the hemisphere by bundles of fibres which are called the stalks or peduncles of the thalamus; they are the frontal, the parietal, the temporal and the occipital.

The frontal peduncle consists of fibres which emerge from the antero-lateral part of the thalamus and pass, in the anterior part of the internal capsule, to the frontal area of the cortex of the hemisphere. The parietal peduncle springs from the lateral part of the thalamus and passes partly through the internal and external capsules, and partly through the lentiform

nucleus, to the parietal lobe and the posterior part of the frontal lobe. The temporal peduncle or ventral stalk is formed by fibres which spring from the cells of the medial and lateral nuclei. They issue from the lower surface of the anterior part of the thalamus and pass, below the lentiform nucleus, to the temporal lobe and the insula. The occipital peduncle springs from the lateral side of the posterior end of the thalamus, in the region of the pulvinar, and its fibres form the optic radiations. They pass through the posterior

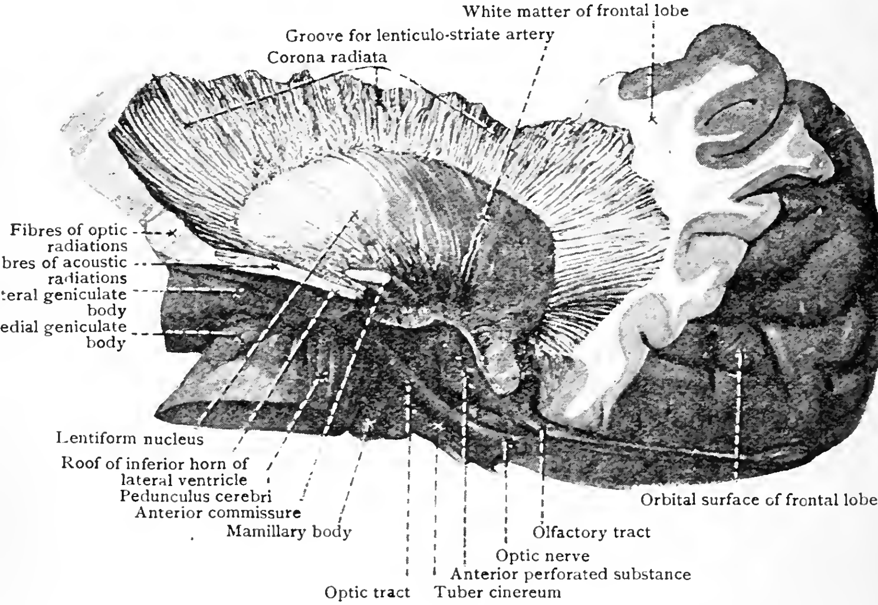

FIG. 189.—Dissection of the right Lentiform Nucleus and the right Corona Radiata from the lateral side.

or retro-lentiform part of the internal capsule and are distributed to the cortex of the occipital lobe, especially in the region of the calcarine fissure (Figs. 182, 191).

Dissection.—Take the lower part of the remains of the right hemisphere and from its lateral side tear away the grey and white matter of the insula, then the claustrum, and, finally, the external capsule, to expose the lateral surface of the lentiform nucleus. As this is being done note the fibres which pass through the region of the limen insulæ and connect together the frontal and the temporal lobes; they constitute the *fasciculus uncinatus*. Note also that the white layer which lies below the lentiform nucleus contains—(1) In its posterior part, the fibres of the acoustic radiations; (2) In its anterior part the fibres of the temporal peduncle of the thalamus; and in addition the fibres of

the anterior commissure pass through it on their way to the temporal lobe. Define the fibres of the anterior commissure (Fig. 189) and trace them forward and medially, to the medial face of the section, by removing the anterior perforated substance, which lies below them.

The fibres which lie anterior and posterior to the lentiform nucleus are fibres of the internal capsule. The anterior fibres can be traced downwards to the basis pedunculi, but those of the posterior part, which are fibres of the acoustic and optic radiations, turn medially towards the posterior part of the thalamus and the medial geniculate body.

Make a similar dissection on the upper segment of the right hemisphere to expose the upper part of the lateral surface and the upper border of the lentiform nucleus. Note that the white matter which appears at the upper border of the lentiform nucleus consists of fibres of the internal capsule, which are passing vertically into the corona radiata, and of some longitudinally directed fibres which form the superior longitudinal fasciculus (Fig. 188). Now remove the lentiform nucleus and expose the remainder of the lateral surface of the internal capsule. Finally, trace the main mass of the capsule downwards into the basis pedunculi of which they form the middle three-fifths; the lateral and medial fifths being formed by fibres passing from the temporal and frontal lobes to the pons. Preserve the pieces of the right hemisphere so that the continuity of the motor fibres of the anterior two-thirds of the posterior division of the capsule with the cerebro-spinal fibres of the pons and medulla can be demonstrated at a later stage.

When the dissection of the right hemisphere is completed turn to the posterior vertical section of the left hemisphere and expose the internal capsule from the lateral side by removing, in turn, the remains of the insula, the claustrum, the external capsule, and the lentiform nucleus; then trace the fibres of the internal capsule of the left side downwards into the basis pedunculi.

Complete the dissection of the right hemisphere by tracing the fasciculus mamillo-thalamicus upwards from the mamillary body into the anterior nucleus of the thalamus.

Capsula Interna.—The internal capsule is a relatively thick lamina of white substance by means of which associations are established between the cortex of the hemisphere, its basal nuclei, the lower parts of the brain, and the medulla spinalis. It lies between the caudate nucleus and the thalamus, on the medial side, and the lentiform nucleus on the lateral side, but it extends both anterior and posterior to the lentiform nucleus, and therefore consists of lentiform, pre-lentiform, and retro-lentiform portions. It is continuous, below, with the basis pedunculi and above with the corona radiata, and the lentiform part is bent upon itself, round the medial angle of the lentiform nucleus. The bend, which is known as the *genu*, lies between, and unites together, the anterior and

posterior divisions of the lentiform portion of the capsule. Through the anterior division, which lies between the lentiform and caudate nuclei, pass the fibres of the anterior peduncle of the thalamus, and fronto-pontine fibres which associate the cells of the frontal part of the cortex of the hemisphere with the nerve cells of the ventral part of the pons. The genu consists of fibres which convey motor impulses from the motor area of the cortex of the hemisphere to the nuclei of the nerves which supply the muscles of the face and tongue of the opposite side. The posterior division of the lentiform

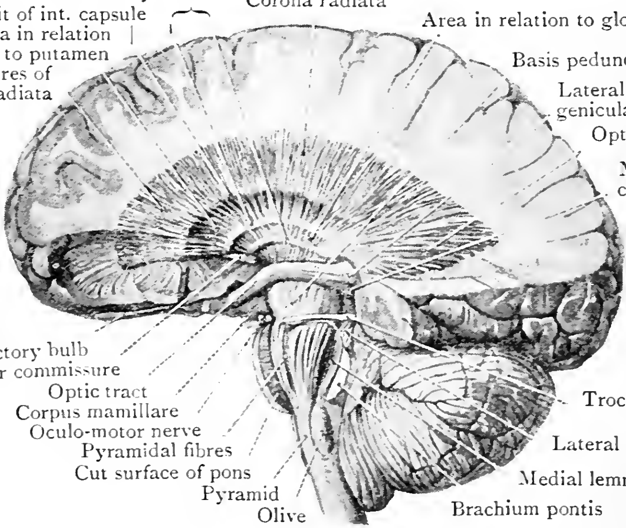

FIG. 190.—Dissection of Internal Capsule and Pyramidal Fibres.

portion of the capsule, which lies between the lentiform nucleus and the thalamus, is separable into (1) an anterior two-thirds, which consists principally of fibres conveying motor impulses to the nuclei of the nerves which supply the muscles of the upper limb, trunk, and lower limb of the opposite side, in that order from before backwards, together with some sensory fibres; and (2) a posterior third, which contains sensory fibres, that is, fibres conveying ordinary sensory impulses to the cortex of the hemisphere. The majority, if not all, of the sensory fibres spring from the thalamus, and they pass to the parietal, occipital, and temporal lobes. The fibres which spring from the posterior part of the thalamus and pass through the posterior or retro-

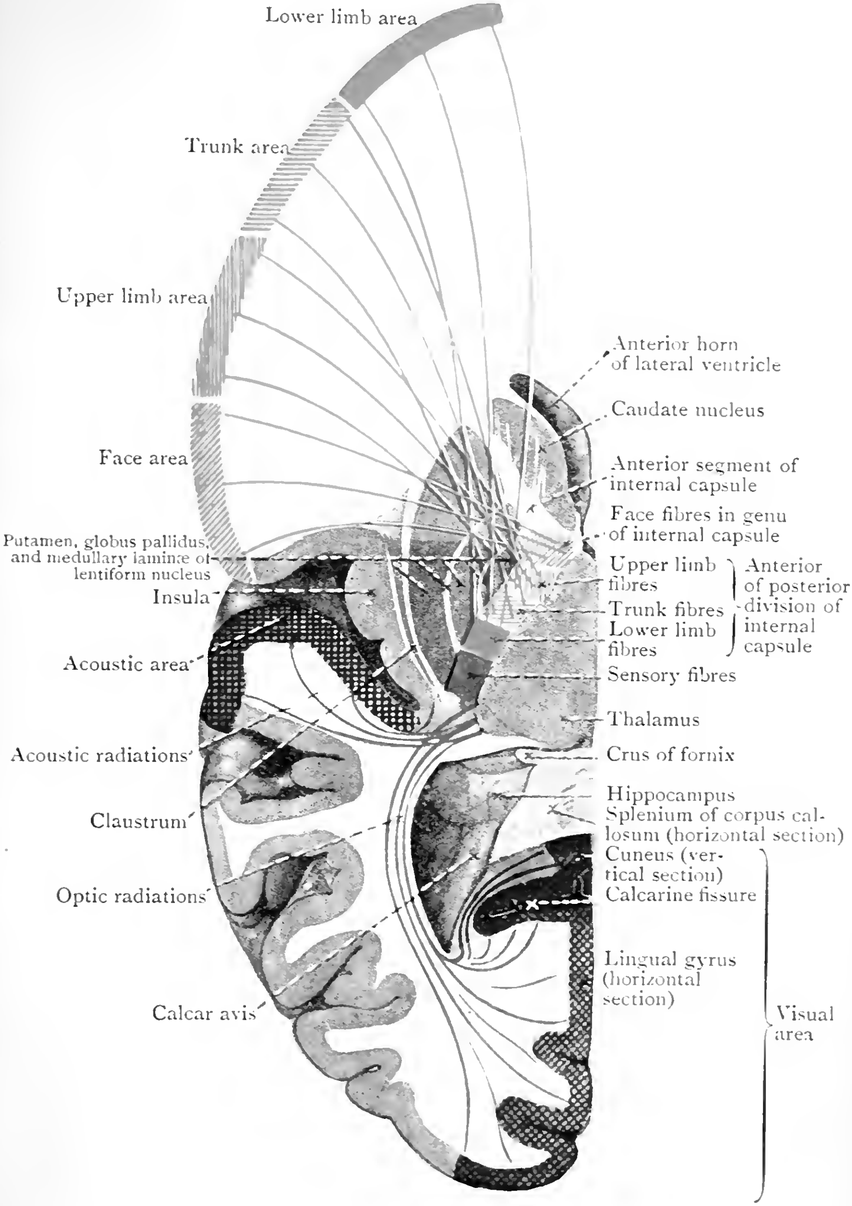

FIG. 191.—Diagram showing the Motor and the Acoustic and Visual Areas of Left Hemisphere and their relations to the Internal Capsule.

The internal capsule and the auditory and visual areas are seen in horizontal section. The motor areas, in red, are supposed to be in vertical section and to be placed at right angles to the horizontal section.

The area of ordinary sensation is not shown, but the fibres from it lie mainly in the posterior third of the posterior division of the internal capsule.

lentiform part of the capsule, and then along the lateral wall of the posterior horn of the lateral ventricle to their distribution in the visual area of the occipital cortex, are called the *optic radiations* (Fig. 191).

Through the posterior part of the internal capsule in the retro-lentiform area, but at a lower level than the optic radiations, there passes a series of fibres, from the medial geniculate body to the temporal lobe, which constitute the *acoustic radiations* (Fig. 191).

Capsula Externa.—The external capsule is a relatively thin lamina of white matter which intervenes between the lentiform nucleus and the claustrum. It is continuous, anteriorly and posteriorly, with the internal capsule, and, above, with the corona radiata. It blends, below, with the sheet of white fibres which separates the lentiform nucleus from the roof of the inferior horn of the lateral ventricle.

THE PARTS OF THE BRAIN WHICH LIE IN THE POSTERIOR CRANIAL FOSSA.

The parts of the brain which lie below the tentorium cerebelli in the posterior cranial fossa are the *lower part of the mid-brain*, the *pons*, the *medulla oblongata*, and the *cerebellum*. The mid-brain has been considered already. The cerebellum, the medulla oblongata, and the pons constitute collectively the rhombencephalon or hind brain, and they are grouped around the *fourth ventricle* of the brain. The fourth ventricle is a cavity which communicates below with the central canal of the medulla spinalis, and above with the aquæductus cerebri.

Medulla Oblongata.—The medulla oblongata is the continuation of the spinal medulla into the brain. It is nearly 30 mm. long (*rather more than one inch*), and may be reckoned as beginning at the level of the foramen magnum. Thence it proceeds upwards, in an almost vertical direction (Fig. 188), and it ends at the lower border of the pons. At first, its girth is similar to that of the spinal medulla, but it rapidly expands as it approaches the pons, and consequently it presents a more or less conical appearance. Its anterior surface lies in the groove on the basilar portion of the occipital bone, and its posterior surface is sunk into the vallecula of the cerebellum.

The bilateral construction of the medulla oblongata is indicated by the appearance of its exterior, for the antero-median and postero-median sulci on the surface of the spinal medulla are prolonged upwards on the anterior and posterior surfaces of the medulla oblongata.

The *antero-median fissure*, as it passes from the spinal medulla on to the medulla oblongata, is interrupted, at the level of the foramen magnum, by several strands of fibres

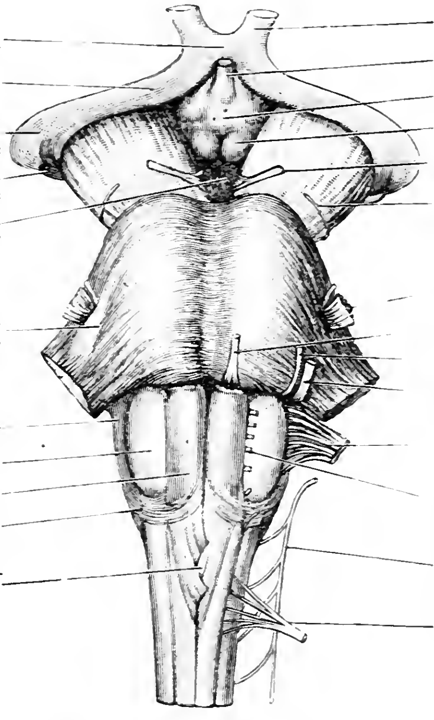

FIG. 192.—Anterior aspect of the Medulla Oblongata, Pons, and Mesencephalon of a full-time Fœtus.

which cross the median plane from one side to the other. This intercrossing is termed the *decussation of the pyramids*. Above the level of the decussation the furrow passes upwards to the lower border of the pons. There it expands slightly, and ends in a blind pit, termed the *foramen cæcum*.

The *postero-median fissure* runs upwards for only half the length of the medulla oblongata. Then the central canal, continued upwards from the medulla spinalis, becomes the fourth ventricle of the brain. As the canal expands dorsally it pushes aside the lips of the posterior median fissure till

the epithelium of the posterior wall of the central canal appears on the surface, and forms the posterior wall or roof of the lower part of the fourth ventricle in the triangular interval between the diverging posterior funiculi of the medulla oblongata.

The surface of each half of the medulla oblongata should now be studied. It is well, however, to defer the examination of the medullary part of the floor of the fourth ventricle till a later period. The dissector has already noticed two linear rows of nerve fila issuing from and entering the medulla oblongata on each side. The *anterior row* consists of the fila of the hypoglossal nerve and the uppermost fila of the anterior root of the first cervical nerve. They continue along the side on the medulla oblongata in the line of the anterior nerve roots of the spinal medulla, and they emerge along the bottom of a more or less distinct groove. The *posterior row* is formed of the nerve fila of the accessory, vagus, and glossopharyngeal nerves. As they enter they lie in series with the posterior roots of the spinal nerves.

By these two rows of nerve fila, each side of the medulla oblongata is divided into three districts, viz., an anterior, a lateral, and a posterior, similar to the surface areas of the three funiculi of each half of the medulla spinalis. At first sight, indeed, they appear to be direct continuations upwards of the funiculi of the spinal medulla; it is easily demonstrated, however, that that is not the case, and that the fibres in the three funiculi of the medulla spinalis undergo a rearrangement as they are traced into the medulla oblongata.

Anterior Area of the Medulla Oblongata—Pyramis.—The district between the antero-median fissure and the row of hypoglossal nerve fila issuing from the medulla receives the name of the *pyramid*. An inspection of the surface is almost sufficient to show that the pyramid is formed by a compact mass of longitudinally directed fibres. It expands somewhat, and assumes a more prominent appearance as it passes upwards, and, finally, as it reaches the lower border of the pons, it becomes slightly constricted and disappears from view by plunging into the pons. The pyramids are the great motor strands of the medulla oblongata.

The pyramid, at first sight, appears to be the continuation upwards of the anterior funiculus of the spinal medulla, but it contains also a large number of fibres which, at a lower

level, lie in the lateral funiculus. That will be realised if the *decussation of the pyramids* is examined. For that purpose introduce the back of the knife-blade into the antero-median fissure below the decussation, and on one side push in a lateral direction the anterior funiculus of the medulla spinalis. The pyramid will then be seen to divide into two

FIG. 193.—Diagram of the Decussation of the Pyramids. (Modified from Van Gehuchten.)

portions, viz., a small strand termed the *fasciculus cerebrospinalis anterior* (O.T. *direct pyramidal tract*), which proceeds downwards into the anterior funiculus of the spinal medulla close to the antero-median fissure, and a much larger strand called the *fasciculus cerebrospinalis lateralis* (O.T. *crossed pyramidal tract*), which, at the level of the decussation, is broken up into three or more coarse bundles which sink backwards and, at the same time, cross the median plane to

take up a position in the opposite lateral funiculus of the spinal medulla, close to the posterior column of grey matter. It is the intercrossing of the corresponding bundles of the lateral cerebro-spinal fasciculi of opposite sides which produces the characteristic decussation.

But whilst the fasciculus cerebrospinalis anterior of the anterior funiculus and the fasciculus cerebrospinalis lateralis of the opposite lateral funiculus of the spinal medulla are

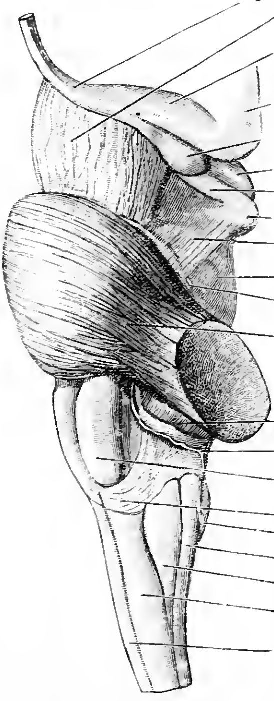

FIG. 194.—Lateral view of the Medulla Oblongata, Pons, and Mesencephalon of a full-time Fœtus.

both represented in one district of the medulla oblongata, it may be asked: What becomes of the larger lateral part of the anterior funiculus of the spinal medulla in the medulla oblongata? It is thrust backwards by the decussating bundles of the lateral cerebro-spinal fasciculus, and occupies a deep position in the medulla oblongata.

Lateral Area of the Medulla Oblongata.—The lateral area is the district on the surface of the medulla oblongata which is included between the two rows of nerve fila, viz., the hypoglossal fila anteriorly, and the fila of the accessory, vagus, and

glosso-pharyngeal posteriorly. It presents a very different appearance in its upper and lower parts. In its lower portion it appears to the eye as a continuation upwards of the lateral funiculus of the spinal medulla; in its upper part the striking oval prominence, named the *olive*, is seen.

The lower part of the district, however, is very far from being an exact counterpart of the lateral funiculus of the spinal medulla. It has been noted already that the large fasciculus cerebrospinalis lateralis, which in the spinal medulla lies in the lateral funiculus, is not present in that district of the medulla oblongata; above the decussation of the pyramids it forms the chief part of the pyramid of the opposite side. Another small strand of fibres, the *dorsal spino-cerebellar fasciculus* (O.T. *direct cerebellar tract*), prolonged upwards in the lateral funiculus of the spinal medulla, gradually leaves the lateral portion of the medulla oblongata. The tract of fibres in question lies on the surface, and it is often visible to the naked eye as a white streak inclining obliquely into the posterior district of the medulla oblongata to join its upper part, which is called the *restiform body*. The great majority of the remainder of the fibres which are prolonged upwards from the lateral funiculus of the spinal medulla disappear from the surface at the lower border of the olive, by dipping into the substance of the medulla oblongata under cover of that projection. A narrow band, however, passes upwards to the pons, in the interval between the posterior border of the olive and the fila of the vagus and glosso-pharyngeal nerves.

The *olive* is a smooth, oval prominence, which occupies the upper part of the lateral area of the medulla oblongata. Its long axis, which is vertical, is about 12.5 mm. (*half an inch*) long, and its upper end is separated from the lower border of the pons by an interval or groove.

Posterior Area of the Medulla Oblongata.—The constituent parts of the lower half of the posterior region are the cuneate and gracile funiculi; in its upper half they are the ependymal roof of the fourth ventricle, medially, and the diverging funiculi, laterally.[1] It is separated from the lateral area on each

[1] The dissector should note that the lower part of the cavity of the hind-brain, *i.e.* the fourth ventricle, is not behind but *in* the upper part of the medulla, which it separates into dorsal and ventral parts; the dorsal part forms a portion of the roof of the ventricle, whilst the ventral part forms a portion of the floor.

side by the row of fila belonging to the accessory, vagus, and glosso-pharyngeal nerves.

The lower part of the posterior area corresponds more or less closely with the posterior funiculus of the spinal medulla. It will be remembered that in the cervical part of the spinal medulla the posterior funiculus, on each side, is divided, by a distinct septum of pia mater, into a postero-median strand, the fasciculus gracilis, and a postero-lateral strand, the fasciculus cuneatus. The two strands are prolonged upwards into

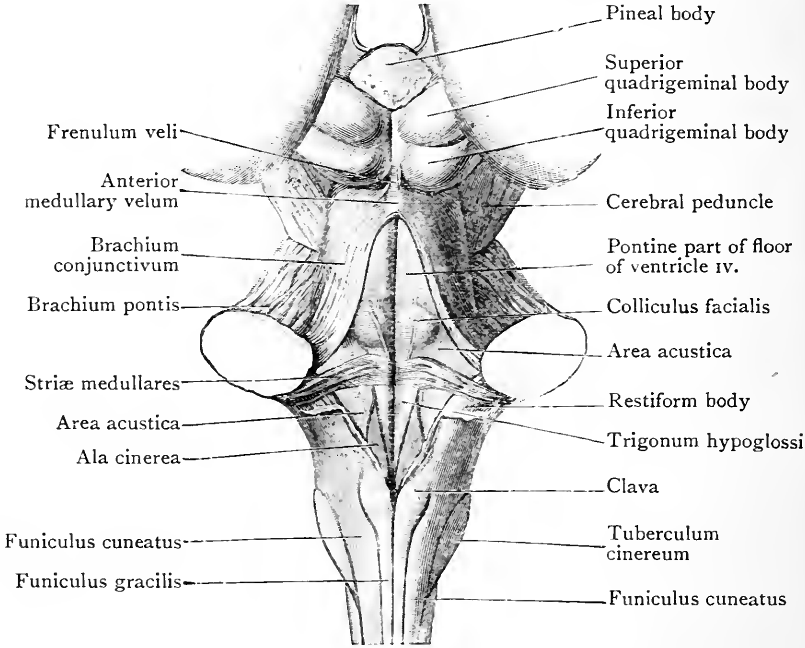

FIG. 195.—Posterior view of the Medulla Oblongata, Pons, and Mesencephalon of a full-time Fœtus. The greater part of the roof of the fourth ventricle is removed.

the medulla oblongata. In the lower part of the posterior area they stand out distinctly, and are separated from one another by the postero-intermediate sulcus, which is continued upwards from the medulla spinalis. Each strand, when it reaches the lower part of the fourth ventricle, ends in a slightly expanded prominence. The swollen extremity of the fasciculus gracilis is called the *clava*; it is thrust aside from its fellow of the opposite side by the opening up of the central canal to form the fourth ventricle.

In sections at the level of the lower part of the fourth

ventricle, it is seen that the prominences produced by the two strands and their enlarged extremities are in a great measure due to the presence of two elongated nuclei, which lie subjacent to them and gradually increase as they are traced upwards. These are termed the *gracile* and the *cuneate nuclei*, and as the grey matter increases in quantity the fibres of the two corresponding strands diminish in number. Indeed, it is doubtful if any of the fibres are prolonged upwards beyond the level of the nuclei.

But a third longitudinal elevation also is apparent in the lower part of the posterior area of the medulla oblongata. It is placed on the lateral side of the fasciculus cuneatus—between it and the posterior row of nerve fila—and it has no counterpart in the posterior funiculus of the spinal medulla. It is called the *funiculus of Rolando*, because it is produced by the substantia gelatinosa (Rolandi) approaching the surface. Extremely narrow below, the funiculus of Rolando widens somewhat as it is traced upwards, and it, finally, ends in an expanded extremity called the *tuberculum cinereum*. The thin layer of fibres which appear on the surface of the tuberculum cinereum, and cover the substantia gelatinosa (Rolandi), in that position, belong to the tractus spinalis (O.T. spinal root) of the trigeminal nerve.

The *restiform body* forms the upper part of the posterior area on each side. It lies between the lower part of the floor of the fourth ventricle and the fila of the vagus and glosso-pharyngeal nerves, and is thrust laterally by the enlargement of the fourth ventricle. It is a relatively large rope-like strand, which inclines upwards and laterally, and then, finally, it takes a turn backwards, and enters the cerebellum, of which it constitutes the *inferior peduncle*. The restiform body, therefore, is to be regarded as the main connection between the cerebellum, above, and the medulla oblongata and medulla spinalis, below. At the same time, it must be understood that it is not formed of fibres which are prolonged into it from the fasciculus gracilis and fasciculus cuneatus of its own side, although a surface inspection of the medulla oblongata might lead very naturally to that supposition, because there is no sharp line marking it off from the ends of those strands.

The fibres which build up the restiform bodies come from several different sources. It will be sufficient to indicate the more important of them—

(1) fibres from the lateral funiculus of the spinal medulla, through the *dorsal spino-cerebellar fasciculus*; (2) *olivo-cerebellar fibres* from the opposite inferior olivary nucleus to the cerebellum; (3) fibres from the cuneate and gracile nuclei of both sides in the form of the *arcuate fibres*.

Fibræ Arcuatæ Externæ.—On the surface of the medulla oblongata, more particularly in the neighbourhood of the lower border of the olive, a number of curved bundles of fibres, termed the *external arcuate fibres*, may be noticed. They vary greatly in number and in distinctness, and are sometimes so numerous as to cover the olive almost entirely. An attentive examination will show that they come to the surface (1) in the antero-median fissure between the pyramids, (2) in the groove between the pyramid and the olive, and (3) sometimes also through the substance of the pyramids. But at whatever point they reach the surface, the majority have one destination, viz., the restiform body—a considerable part of which they form. They are derived from the cuneate and gracile nuclei of the opposite side, and end in the cerebellum.

At the inferior end of the olive there is not uncommonly a curved bundle of fibres, called the *circum-olivary fasciculus*, which follows the line of the external arcuate fibres but has a different commencement and termination. It consists of fibres descending from the cerebrum, and corresponds with the fibres of the pons which end round the pontine nuclei.

Dissection.—The pyramidal fibres of one side should now be carefully raised. When dislodged from their bed they should be gently pulled upwards towards the pons. In that way their entrance into the pons will be brought very clearly into view. Further, numerous arcuate fibres will be seen running forwards upon the medial aspect of the opposite pyramid to reach the surface, and the ventral edge of the medial lemniscus will be exposed also.

Pons.—The pons is the marked prominence, on the base of the brain, which lies anterior to the cerebellum and is interposed between the medulla oblongata and the pedunculi cerebri (Figs. 160, 194). It is convex from side to side, as well as from above downwards, and the transverse streaks on its surface show that, superficially, it is composed of transverse bundles of nerve fibres. On each side the transverse fibres collect themselves together to form a large compact strand which sinks, postero-laterally, into the corresponding hemisphere of the cerebellum. The strand is termed the *brachium pontis* (O.T. *middle cerebellar peduncle*).

When the brain is *in situ* the *ventral surface* of the pons is in relation to the basilar portion of the occipital bone, the

dorsum sellæ of the sphenoid bone, and the medial parts of the posterior surfaces of the petrous portions of the temporal bones. It presents a median groove which gradually widens as it is traced upwards (Fig. 192). The groove lodges the basilar artery, but is not caused by that vessel; it is due to the prominence produced, on each side, by the passage downwards, through the pons, of the bundles of fibres which form the pyramids of the medulla oblongata. Where the pons becomes the brachium pontis the large trigeminal nerve is attached to its ventral surface, nearer its upper than its lower border.

With the exception of the restiform bodies, which pass backwards into the cerebellum, most of the constituent parts of the medulla oblongata are continued into the pons. The pedunculi cerebri emerge from the upper aspect of the pons.

The *dorsal surface* of the pons cannot be studied at present. It is turned towards the cerebellum, which hides it from view, and it forms the upper part of the anterior boundary or floor of the fourth ventricle.

Cerebellum.—The cerebellum is distinguished by the numerous parallel and more or less curved sulci which traverse its surface and give it a foliated appearance. As in the case of the cerebral hemispheres, the grey matter is spread over the entire surface, whilst the white matter forms a central core in the interior.

The cerebellum consists of a median portion, the *vermis*, and two *hemispheres*, but the distinction between those main subdivisions of the organ is not very evident on its superior surface. Anteriorly and posteriorly there is a marked deficiency or notch in the median plane (Fig. 197). The *posterior notch* is smaller and narrower than the anterior notch. It is bounded on each side by the posterior parts of the cerebellar hemispheres, and anteriorly by the vermis, and it is occupied by the falx cerebelli. The *anterior notch* is much wider and, when viewed from above, it is seen to be occupied by the inferior colliculi of the quadrigeminal lamina and the brachia conjunctiva cerebelli. Its sides are formed by the hemispheres, and the posterior end is bounded by the vermis.

On the *superior surface* of the cerebellum there are, as already stated, no definite lines of demarcation between the vermis and the upper surfaces of the hemispheres. The upper

part of the vermis forms a median ridge, from which the surface slopes gradually downwards, on each side, to the margin of the corresponding hemisphere. On the upper part of the vermis four regions are recognised. Anteriorly, at the posterior end of the anterior notch, lies the *central lobe*, and prolonged upwards from it on the dorsal surface of the anterior medullary velum, between the brachia conjunctiva, are a few folia which constitute the *lingula*. Posterior to the central lobe is the *monticulus*, separable into two parts—an anterior, more elevated portion, the *culmen*, and a posterior, sloping ridge, the *declive*. Posterior to the declive, in the anterior boundary of the posterior notch, lies a single folium called the *folium vermis*.

On the *inferior surface* of the cerebellum, the distinction between the three constituent parts of the organ is much better marked. On that aspect the hemispheres are full, prominent and convex, and they are separated by a deep, median hollow which is continued forwards from the posterior notch. The hollow is termed the *vallecula cerebelli*, and in its anterior part the medulla oblongata is lodged. If the medulla is forced away from the cerebellum, and the hemispheres are pulled apart so as to expose the upper boundary of the vallecula, it will be seen that that boundary is formed by the inferior surface of the *vermis*, and, further, that the vermis is separated, on each side, from the corresponding hemisphere by a distinct furrow, termed the *sulcus valleculæ*.[1]

If the margin of the vermis, where it forms the posterior boundary of the anterior notch on the superior aspect of the cerebellum, is gently raised, and at the same time the mesencephalon is pulled forwards, two strands lying upon the dorsal aspect of the pons will be seen. These are the *brachia conjunctiva cerebelli* (O.T. *superior peduncles*). They emerge from the white matter of the cerebellum, converge as they proceed upwards, and, finally, they disappear under the inferior quadrigeminal bodies. The thin lamina which is stretched across between them is the *anterior medullary velum*. It is continuous below with the white core of the vermis, and it helps to form the roof of the upper part of the fourth ventricle. From its dorsal surface, close

[1] As the medulla oblongata is displaced forwards, and the hemispheres of the cerebellum are pulled apart, the epithelial roof of the fourth ventricle and its covering of pia mater will be torn away, and the lower part of the floor or anterior boundary of the fourth ventricle will be displayed.

to the inferior quadrigeminal body, the small trochlear nerves emerge.

Certain of the sulci which traverse the surface of the cerebellum, deeper and longer than the others, map out districts which are termed lobes. The most conspicuous of all the clefts is the *horizontal sulcus.*

Sulcus Horizontalis Cerebelli.—The horizontal sulcus begins anteriorly, where its lips separate from one another to enclose the large brachia pontis, and it passes round the

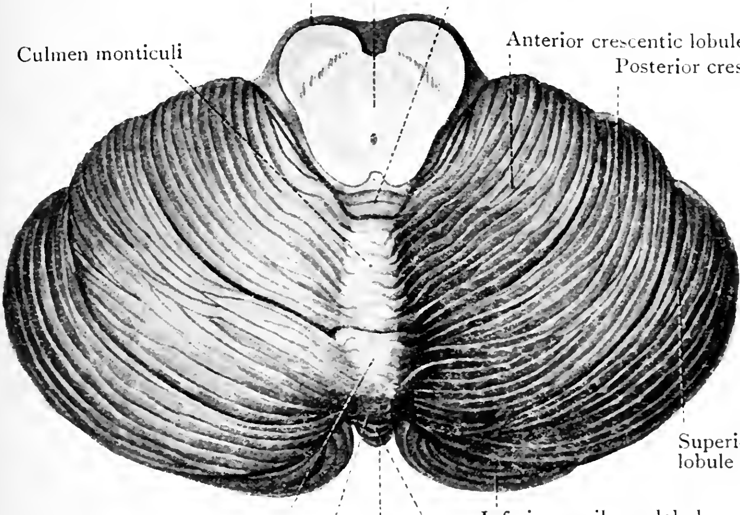

FIG. 196.—Upper surface of the Cerebellum.

circumference of the cerebellum, cutting deeply into its lateral and posterior margins. By means of the horizontal sulcus the cerebellum is divided into an upper and a lower part, which may be studied separately.

Lobes on the Upper Surface of the Cerebellum.—It has been noted already that the upper surface of the vermis superior is subdivided. The divisions, commencing at the anterior end, are:—(1) the lingula; (2) the central lobule; (3) the culmen monticuli; (4) the declive monticuli; (5) the folium vermis. With the exception of the lingula, each part is continuous on each side with a corresponding district on the upper surface of the hemisphere, and forms with those districts a cerebellar lobe. Thus, the central lobule is prolonged laterally on each side in an expansion called the *ala*;

the culmen constitutes a median connecting piece between the two *anterior crescentic lobules* of the hemispheres ; the declive stands in the same relation to the *posterior crescentic lobules* ; and the folium vermis is the connecting band between the *superior semilunar lobules* of the hemispheres.

Lingula.—The lingula can be seen only when the posterior boundary of the anterior notch is pushed backwards. It consists of four or five small folia, continuous with the grey matter of the vermis, prolonged upwards on the surface of the anterior medullary velum, in the interval between the brachia conjunctiva.

Lobus Centralis with its Alæ.—The central lobule lies at the posterior

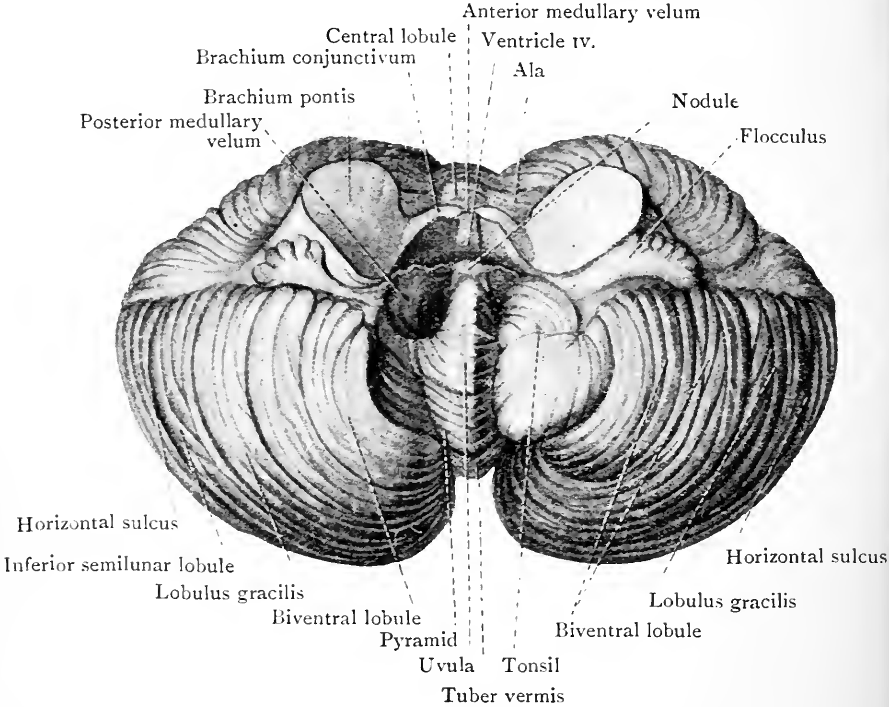

FIG. 197.—Lower surface of the Cerebellum. The tonsil of the right side has been removed so as to display the posterior medullary velum and the furrowed band.

end of the anterior notch, and is largely hidden by the culmen. It is a little median mass which is prolonged laterally for a short distance round the semilunar notch in the form of two expansions, termed the *alæ*.

Lobus Culminis.—The *culmen monticuli* constitutes the summit or highest part of the monticulus of the vermis. It is prolonged laterally on each side into the corresponding hemisphere as the *anterior crescentic lobule*. This is the most anterior subdivision on the upper surface of the hemisphere. The two anterior crescentic lobules, with the culmen monticuli, form the *lobus culminis cerebelli.*

Lobus Declivis.—The *declive monticuli* lies posterior to the culmen, from which it is separated by a distinct fissure, and it forms the sloping part or descent of the monticulus of the vermis. On each side it is continuous

with the *posterior crescentic lobule* of the hemisphere, and the three parts are included under the one name of *lobus declivis*.

The two crescentic lobules on the upper surface of the hemisphere are frequently described together as the *quadrate lobule*.

Lobus Semilunaris Superior (O.T. **Lobus Cacuminis**).—The *folium vermis* forms the most posterior part of the superior portion of the vermis, and it bounds the horizontal fissure, superiorly, at the posterior notch. It is a single folium, the surface of which may be smooth or notched with rudimentary secondary folia, and it is the connecting link between the two *superior semilunar lobules* of the hemispheres—the three parts constituting the *lobus semilunaris superior*. As the folium vermis is traced laterally into the semilunar lobule of the hemisphere, it is found to expand greatly. The result is that the lobus semilunaris superior, on each side, forms an extensive foliated district bounding the posterior part of the horizontal sulcus superiorly.

Lobes on the Lower Surface of the Cerebellum.—The connection between the several portions of the inferior part of the vermis, and the

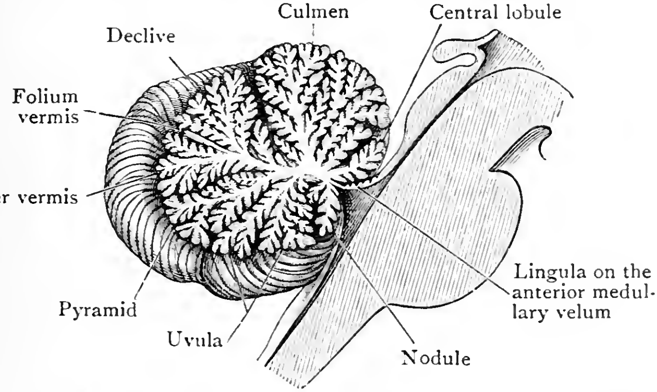

FIG. 198.—Median section through the Vermis of the Cerebellum. (From Gegenbaur.)

corresponding districts on the inferior surface of the two hemispheres is not nearly so distinct as in the case of the superior part of the vermis and the lobules on the upper surface of the hemispheres.

The following subdivisions of the inferior part of the vermis are recognised, from behind forwards—(1) the tuber vermis, (2) the pyramid, (3) the uvula, and (4) the nodule.

On the inferior surface of the hemisphere there are five lobules mapped out by intervening sulci. They are—(1) the *flocculus*, a little lobule lying on the brachium pontis; (2) the *biventral lobule*, which lies immediately posterior to the flocculus, and is partially divided into two parts by a fissure which traverses its surface; (3) the *tonsil*, a rounded lobule, which bounds the vallecula on the medial side of the biventral lobule; (4) the *inferior semilunar lobule*, placed posterior to the biventral lobule, and bounding the horizontal sulcus inferiorly.

The lobules of the inferior parts of the hemispheres, with the corresponding portions of the inferior part of the vermis, constitute the lobes on the inferior aspect of the cerebellum.

Lobus Noduli.—The lobus noduli comprises the nodule and the flocculus, of each side, with an exceedingly delicate connecting lamina of white matter, termed the *posterior medullary velum*.

The velum cannot be properly seen at present, but it will be exposed at a later stage of the dissection.

Lobus Uvulæ.—The uvula is a triangular elevation placed between the two tonsils. It is connected, across the sulcus valleculæ, with each tonsil by a low-lying ridge of grey matter which is scored by a few shallow furrows, and in consequence termed the *furrowed band.* The two tonsils and the uvula form the *lobus uvulæ.*

To see the furrowed band it will be necessary to remove the tonsil on one side, when the posterior medullary velum also will be exposed.

Lobus Pyramidis.—The pyramid is connected with the biventral lobule on each side by a faint ridge which crosses the sulcus valleculæ. The term *lobus pyramidis* is given to the three lobules which are thus associated with each other.

Lobus Tuberis.—The *tuber vermis*, which forms the most posterior part of the inferior vermis, is composed of several folia, which run directly into the inferior semilunar lobule on each side. The three parts of the *lobus tuberis* are thus linked together. The inferior semilunar lobule is traversed by two, or it may be three, curved fissures. The most anterior of these cuts off a narrow, curved strip of cerebellar surface called the *lobulus gracilis.*

Dissection.—A median section should now be made through the vermis of the cerebellum and the two medullary vela into the cavity of the fourth ventricle. When the two parts of the cerebellum are drawn slightly asunder, a view of the fourth ventricle is obtained; further, the connections of the two medullary vela and the arrangement of the peduncles of the cerebellum can be more clearly understood.

Arbor Vitæ Cerebelli.—The cut surface of the cerebellum presents a very characteristic appearance. The grey matter on the surface stands out distinctly from the white matter in the interior. Further, the complete manner in which the surface is cut up by the sulci into secondary and tertiary folia is seen. The central mass of white matter in the vermis is termed the *corpus medullare.* From the corpus medullare, prolongations pass into the various lobules, and they give off branches to supply each folium with a central white stem or core. The term *arbor vitæ* is applied to the appearance which consequently results when a section is made through the cerebellum (Fig. 198).

Cerebellar Peduncles.—The cerebellar peduncles are the structures which connect the cerebellum with the medulla oblongata, the pons and the mid-brain. They are three in number on each side—viz., the inferior, the middle, and the superior. They are all directly connected with the white medullary centre of the cerebellum, and are composed of fibres which emerge from or enter the white central substance of the organ.

The *middle peduncle* or brachium pontis is much the

largest of the three. It is formed by the transverse fibres of the pons, and it enters the cerebellar hemisphere on the lateral side of the other two. The lips of the anterior part of the horizontal sulcus are separated widely from each other to give it admission (Fig. 195).

The *inferior peduncle* is the restiform body of the medulla oblongata. As it leaves the dorsum of the medulla oblongata it turns sharply backwards and enters the cerebellum between the other two peduncles.

The *superior peduncles* are the brachia conjunctiva of the cerebellum. They are composed of fibres which come, for the most part, from the nucleus dentatus of the cerebellar hemisphere. As they issue from the cerebellum, the peduncles lie close to the medial sides of the corresponding middle peduncles. They then proceed upwards towards the inferior pair of quadrigeminal bodies. At first they form the lateral boundaries of the upper part of the fourth ventricle, but they converge, as they ascend on the dorsal aspect of the pons, so that ultimately they overhang the fourth ventricle and enter into the formation of its roof. They disappear under cover of the inferior colliculi of the quadrigeminal lamina, and their course in the mesencephalon has been described already (Figs. 180, 181, 194, 195) (p. 457).

Medullary Vela.—The medullary vela are closely associated with the peduncles. They consist of two thin laminæ of white matter which are projected out from the white central core of the cerebellum. The *anterior medullary velum* stretches across the interval between the two brachia conjunctiva (superior peduncles), with the medial margins of which it is directly continuous. It is triangular in form, and is continuous below with the white matter of the cerebellum. Spread out on its dorsal surface is the tongue-shaped prolongation of grey matter from the cortex of the cerebellum which is termed the *lingula*, and issuing from its substance, close to the inferior colliculi of the quadrigeminal lamina, are the two trochlear nerves.

The *posterior medullary velum* is somewhat more complicated in its connections. It presents the same relation to the nodule that the anterior velum presents to the lingula. It is a wide thin lamina of white matter—so thin that it is translucent—which is prolonged out from the white centre of the cerebellum above the nodule. From the nodule it

stretches laterally to the flocculus, thereby bringing those two small portions of the cerebellum into association with each other. Where it issues from the white matter of the cerebellum it might almost be said to be in contact with the anterior medullary velum, but as the two laminæ are traced forwards they diverge from each other: the anterior velum is carried upwards between the brachia conjunctiva of the cerebellum, whilst the posterior medullary velum turns downwards, round the nodule, and ends in a slightly thickened free crescentic edge. The cavity of the fourth ventricle passes backwards between the two vela, which form a tent-like roof for it.

Isthmus Rhombencephali.—If the dissector examines the rhombencephalon from the side he will recognise that there is a region below the lamina quadrigemina and above the cerebellum which is bounded dorsally by the anterior medullary velum, laterally by the brachia conjunctiva, and ventrally by the upper part of the pons; it is to that region that the term isthmus rhombencephali is applied. It contains the upper part of the fourth ventricle.

Ventriculus Quartus.—The fourth ventricle is somewhat rhomboidal in form. Below, it tapers to a point and becomes continuous with the central canal of the lower part of the medulla oblongata; above, it narrows, in a similar manner, and is continued into the aquæductus cerebri of the mid-brain. The anterior wall is termed the *floor*, and is formed by the dorsal surface of the pons and the ventral part of the upper portion of the medulla oblongata. The posterior wall is called the *roof*. On each side a narrow pointed prolongation of the widest part of the ventricular cavity passes laterally round the upper part of the corresponding restiform body. The prolongations are termed the *lateral recesses* and are seen to the greatest advantage when the cerebellum is divided in the median plane and the halves are turned aside.

The lateral boundary of the fourth ventricle, on each side, is formed, from below upwards, by the clava, the upper part of the fasciculus cuneatus, the restiform body or inferior peduncle of the cerebellum, the brachium pontis or middle peduncle of the cerebellum, and the brachium conjunctivum or superior peduncle of the cerebellum.

Dissection.—On one side cut through the brachium conjunctivum, the brachium pontis and the restiform body, and so

separate one half of the cerebellum, which must be laid aside for the present, but must be preserved for future use.

When the dissection is completed the dissectors will be able to recognise that the anterior part of the cavity of the fourth ventricle is rhomboidal in form. It constitutes the so-called *rhomboid fossa*, which is surrounded by the lateral boundaries of the ventricle and closed anteriorly by the pons and the dorsal surface of the ventral part of the upper half of the medulla oblongata. Only the *lower part* of the rhomboid fossa lies in the medulla oblongata; the *middle part* is in the metencephalon, that is, it lies anterior to the cerebellum and posterior to the lower part of the pons; and the *upper part* is in the isthmus rhombencephali.

The *lower part of the rhomboid fossa* is triangular in outline, and its inferior angle is continuous with the central canal of the lower part of the medulla oblongata. The anterior boundary or floor of this part of the fossa is marked by a number of converging sulci, and is called the *calamus scriptorius.* Along the lateral margins of the lower part of the fossa will be seen the remains of the torn epithelial roof of the lower part of the fourth ventricle. The torn margins are the *tæniæ of the fourth ventricle.* The *middle part of the rhomboid fossa* is separable into a lower wider part, which is prolonged laterally, on each side, below and posterior to the restiform body, as the *lateral recess of the fourth ventricle.* The upper section of the intermediate part of the fossa is bounded laterally by the brachia pontis and is much narrower than the lower part. The *upper part of the rhomboid fossa* lies posterior to the pons and between the brachia conjunctiva. At its upper end it becomes continuous with the aquæductus cerebri of the mid-brain.

The *floor, or anterior boundary, of the fossa rhomboidea* is the floor, or anterior boundary, of the fourth ventricle. In the upper part of its extent it is formed by the posterior surface of the pons, and in the lower part by the posterior surface of the ventral part of the upper portion of the medulla oblongata. It is divided into lateral portions by a *median sulcus* which is deeper below, in the region of the calamus scriptorius, and shallower above. On each side of the median sulcus is the *eminentia medialis.* In the upper part of the fossa the eminentia medialis occupies practically the whole of each half of the floor; in the upper part of the middle

portion of the fossa a rounded eminence, the *colliculus facialis*, appears on its surface; below the colliculus the eminentia medialis narrows rapidly, and its terminal, tapering portion is called the *trigonum hypoglossi.* The medial eminence is bounded laterally by a sulcus, the *sulcus limitans.* In the upper region, along the lateral border of the sulcus limitans, is a narrow bluish-tinted area called the *locus cœruleus*; the colour of that area is due to a subjacent collection of pigmented cells which constitute the *substantia ferruginea.* Opposite the colliculus facialis the sulcus limitans expands into a shallow fossa, the *superior fovea.* The lower end of the sulcus limitans terminates, in the upper part of the inferior section of the rhomboidal fossa, in a definite depression, the *inferior fovea.* To the lateral side of the superior and inferior foveæ and the middle part of the sulcus limitans is the *area acustica*, which is prolonged laterally towards the lateral recess, and, in rare cases, a prominence, the *tuberculum acusticum*, appears on its surface. Below the inferior fovea, between the trigonum hypoglossi medially and the area acustica laterally, lies a depressed, grey-coloured, triangular area called the *ala cinerea*, which is separated from the lower part of the floor, the *area postrema*, by a raised bundle, the *funiculus separans.* Immediately above the inferior fovea a number of ridges, the *medullary striæ* (O.T. *striæ acusticæ*), cross the floor of the fossa transversely. Laterally, they cross the restiform body, at the lateral border of the fossa, and become continuous with the cochlear root of the acoustic nerve; and, medially, they disappear into the median sulcus (Fig. 195).

The *roof of the fourth ventricle* is formed, in the upper area, by the medial parts of the brachia conjunctiva and the intervening anterior medullary velum. Descending upon the velum, from above, is the frenulum veli; issuing from it, in the same region, are the rootlets of the trochlear nerves. The lower part of the upper portion of the roof is covered by the lingula of the cerebellum. The roof of the intermediate section of the ventricle is the white matter of the vermis of the cerebellum, and the roof of the lower part is reduced to the lining epithelial ependyma with the posterior medullary velum, and the obex (see p. 493).

The *tela chorioidea of the fourth ventricle* is the layer of pia mater which covers and strengthens the epithelial roof of the lower part of the cavity. Between it and the epithe-

lium, at the lower end of the roof, is a thin layer of grey matter, called the *obex*. Above, at the posterior medullary velum, the tela becomes continuous with the pia mater on the lower surface of the vermis of the cerebellum. Laterally the tela is prolonged, on each side, posterior to the restiform body, over the lateral recess, and it forms the stronger part of the wall of that expansion. Between the median part of the tela chorioidea of the fourth ventricle and the pia mater on the lower surface of the vermis of the cerebellum lies the cisterna cerebello-medullaris (O.T. cisterna magna) (Fig. 141).

Apertures in the Tela Chorioidea of the Fourth Ventricle.—In the early stages of development the tela chorioidea and ependyma form an unbroken layer, but at a later period three apertures appear in them. One of the apertures, the *apertura medialis ventriculi quarti* (O.T. *foramen of Magendie*), lies immediately above the obex, at the lower angle of the ventricle, and through it the cavity of the fourth ventricle communicates with the cerebello-medullary portion of the subarachnoid space. The other two apertures lie at the apices of the lateral recesses, immediately posterior to the fila of the glossopharyngeal nerves.

Chorioid Plexuses of the Fourth Ventricle.—The chorioid plexuses are invaginations of the ependyma caused by vascular prolongations of the tela chorioidea. In the lower part of the ventricle they form two parallel bands, one on each side of the median plane, and their lower ends project through the median aperture. At the upper part of the tela chorioidea they communicate together, and then each passes laterally into the corresponding lateral recess and their lateral extremities project through the lateral apertures.

Dissection.—The dissector should now introduce his fingers into the horizontal sulcus of that half of the cerebellum which is still connected with the medulla oblongata and the pons, and tear the upper part of the cerebellum away from the lower part. By that proceeding the manner in which the peduncles enter the white medullary centre, and also, to some extent, the general distribution of their fibres, will be seen.

Next, separate the remains of the cerebellum from the isthmus, the pons, and the medulla oblongata by cutting through the peduncles at the points where they enter the central white matter. A horizontal section may then be made through the other half of the organ, rather nearer its upper surface than its lower surface. The section will reveal the nucleus dentatus.

Nucleus Dentatus.—The dentate nucleus is a collection

of grey matter embedded in the white medullary centre of the hemisphere of the cerebellum. Its appearance is very similar to that of a nucleus which lies in the olive of the medulla oblongata. It is a thin lamina of grey matter, which appears, on section, as a wavy line folded upon itself so as to form a crumpled grey capsule with a mouth open towards the median plane. The greater number of the fibres which build up the brachium conjunctivum issue from its mouth.

There are other smaller isolated nuclei of grey matter in the white medullary centre of the cerebellum. They are: the *nucleus emboliformis*, which lies close to the hilum of the dentate nucleus; the *nucleus globosus*, medial to the nucleus emboliformis; and the *nucleus fastigii*, or *roof nucleus*, which is situated in the white matter above the cavity of the fourth ventricle. As a rule, those nuclei cannot be demonstrated in a specimen obtained in the dissecting-room.

Dissection.—Place the lower part of the mid-brain in relation with the upper part, in which the position of the motor fibres, descending from the cortex of the hemisphere, through the anterior part of the posterior division of the internal capsule, has already been defined. Note the position of the motor fibres in the basis pedunculi of the lower part of the mid-brain. They lie, for the main part, in the intermediate three-fifths. On one side trace the motor tract downwards to the upper border of the pons. Then remove the superficial transverse fibres of the pons and trace the motor tract downwards, through the pons. At the lower border of the pons it will be found to become continuous with the ventral (anterior) part of the pyramid of the medulla oblongata. The dissector should note that the tract diminishes somewhat in size as it is followed downwards through the pons.[1] The diminution is due to some of the fibres leaving the tract and passing across the median plane to the nuclei of the cerebral motor nerves of the opposite side. Note that, when the motor tract reaches the lower end of the medulla oblongata, the majority of its fibres cross to the opposite side, to form the lateral cerebro-spinal fasciculus of the lateral funiculus of the spinal medulla of that side, and that the smaller number continue to descend on the same side, to form the anterior cerebro-spinal fasciculus of the anterior funiculus of the same side of the spinal medulla.

Remove the motor tract in the lower part of the mid-brain and in the pons and medulla oblongata, and note the following structures which lie dorsal to it—(1) In the mid-brain a dark pigmented layer, the substantia nigra. (2) In the pons a deep layer of transverse fibres which constitute the corpus trapezoideum. (3) In the medulla oblongata a band of longitudinal white fibres which form part of a long strand called the medial lemniscus.

Lemniscus Medialis.—In the lower part of the medulla

[1] The dissector should note also that other fibres which end in the pons, round the pontine nuclei, are associated with the motor fibres.

oblongata the medial lemniscus consists of fibres which have ascended from the lateral and the anterior funiculi of the spinal medulla, where they form tracts called the lateral and the anterior spino-thalamic fasciculi. In the upper part of the medulla oblongata the spino-thalamic fasciculi are joined

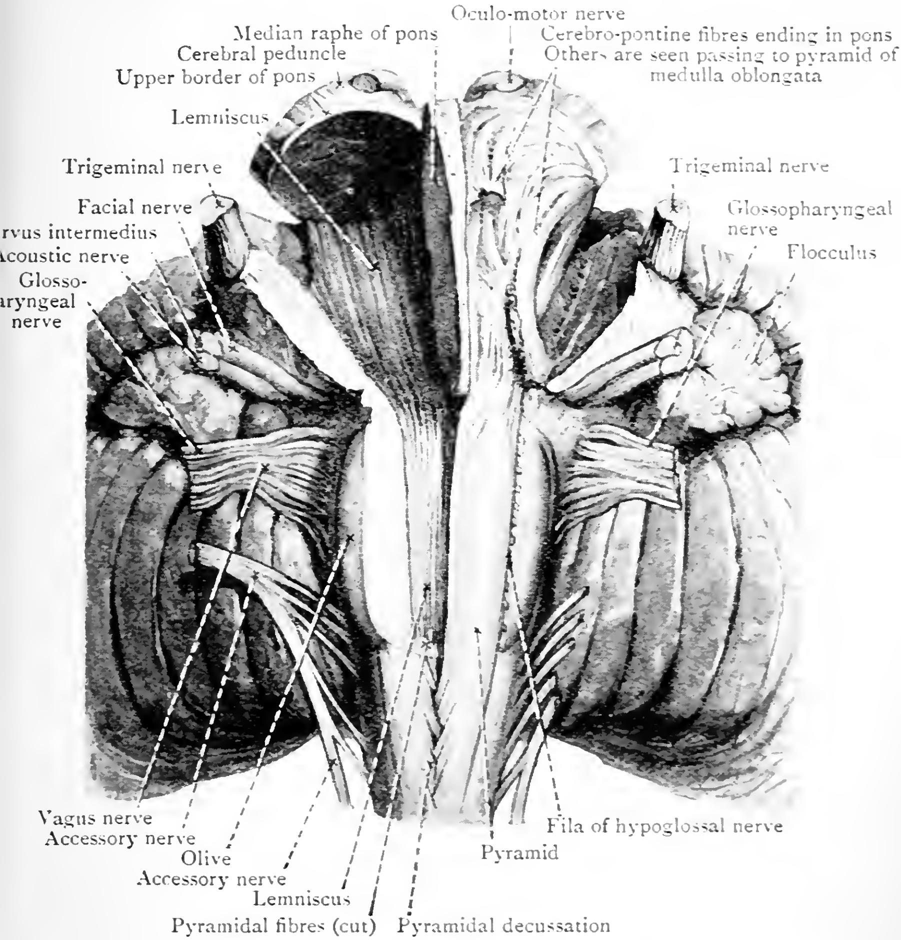

FIG. 199.—Dissection of Pons and Medulla Oblongata to show Pyramidal Fibres and Lemniscus.

by fibres derived from the nucleus gracilis and the nucleus cuneatus of the opposite side. The nucleus gracilis and the nucleus cuneatus lie in the upper ends of the fasciculi of the same names, and the fibres which pass from them to the lemniscus of the opposite side decussate with similar fibres derived from the opposite gracile and cuneate nuclei, in the

region between the olivary bodies, and as they decussate they form the *decussation of the lemnisci* or interolivary decussation (Fig. 201).

In addition to the fibres derived from the spino-thalamic fasciculi and the nucleus gracilis and nucleus cuneatus of the opposite side, the lemniscus, whilst it is still in the medulla oblongata, receives fibres from the sensory nuclei of the cerebral nerves of the opposite side.

The portion of the lemniscus found in the medulla oblongata is known as the *medial lemniscus.* It ascends through the pons into the mid-brain, where many of its fibres end in the superior colliculus, but some ascend still higher and terminate in the thalamus of the same side. As the medial lemniscus ascends through the pons it receives additional fibres from the nuclei of the sensory cerebral nerves of the opposite side. The majority of the additional fibres pass to the lemniscus through the corpus trapezoideum, and those derived from the nuclei of the cochlear division of the opposite acoustic nerve attain a position at the lateral border of the medial lemniscus, and they form a more or less separate bundle termed the *lateral lemniscus.* In the region of the upper part of the pons the fibres of the lateral lemniscus turn dorsally, and, after emerging from the upper border of the pons, they cross superficial to the lateral surface of the upper part of the brachium conjunctivum of the cerebellum (Fig. 194), and disappear under cover of the inferior colliculus of the quadrigeminal lamina, and also under the inferior brachium and the medial geniculate body. They terminate in association with the cells of the inferior colliculus, and with those of the medial geniculate body, whence the acoustic radiations already noted (p. 474) pass to the superior temporal gyrus.

Dissection.—To trace the lemniscus upwards it is necessary to remove the deep transverse fibres of the pons, and the substantia nigra of the mid-brain. As the dissector makes the dissection, he should note—(1) That the lemniscus increases in width in the lower part of the pons on account of the accession of fibres from the nuclei of the sensory cerebral nerves of the opposite side. (2) That in the upper part of the pons the lemniscus decreases in width as the lateral portion leaves it to pass to the inferior colliculus.

After the dissector has displayed, as far as possible, the position and connections of the lemniscus he should turn to the brachium conjunctivum of the cerebellum and attempt to demonstrate its associations. It is quite easily recognisable, as it lies behind the upper part of the pons, in the dorso-lateral

boundary of the upper part of the fourth ventricle. There, it should be located, and thence it should be traced backwards into the hemisphere of the cerebellum, of the same side, to the dentate nucleus, and forwards, medial to the lateral lemniscus and ventral to the inferior colliculus, into the tegmental part of the cerebral peduncle. As the fibres are traced into the mid-brain they will be found to approach the corresponding fibres of the opposite side, with which they decussate, in the lower part of the mid-brain, dorso-medial to the medial lemniscus. After decussating they pass upwards to the red nucleus of the opposite side, where the majority terminate.

When the dissections described are completed the dissector should make a series of transverse sections through the opposite half of the medulla oblongata and the pons, or, better still, through the whole of another specimen, if it can be obtained. In such a series of sections he will be able to note some of the points now to be mentioned, but the majority of the details noted are well seen only on specially prepared and stained sections.

Internal Structure of the Medulla Oblongata.—When transverse sections are made through the upper part of the medulla oblongata, a faint line, called the median raphe, is seen in the median plane. It divides the medulla oblongata into two exactly similar halves. The raphe is formed by the close intersection of fibres running in opposite directions.

Each half of the medulla oblongata is composed of—(*a*) strands of white matter; (*b*) grey matter, which is present both in the form of direct continuations into the medulla oblongata of portions of the grey matter of the spinal medulla, and in the form of isolated masses, which are not represented in the spinal medulla; (*c*) the formatio reticularis, a substance which is composed of grey matter coarsely broken up by fibres which traverse it in different directions; and (*d*) neuroglia. The white matter, as in the spinal medulla, is disposed, for the most part, on the surface and the grey matter in the interior, but in the open part of the medulla oblongata the grey matter comes to the surface on its dorsal aspect, and forms the obex (p. 496).

When the grey matter of the spinal medulla is traced up into the medulla oblongata, many striking changes in its arrangement become apparent. Owing to the increase in size of the large wedge-shaped gracile and cuneate fasciculi, the posterior columns of grey matter are pressed laterally, so that they soon assume a position at right angles to the median plane. At the same time, the cuneate and gracile nuclear columns of grey matter, which grow out from the basal portion of the posterior column and underlie the strands of the same name, begin to make their appearance. From the deep aspects of those nuclei, fibres, which take origin within them, stream antero-medially through the neck of the posterior grey column to reach the ventral median raphe. And as they pass ventrally they separate the head from the basal part of the posterior grey column. The basal part of the grey column remains close to the central canal, but the head and the substantia gelatinosa remain near the surface, and, towards the upper part of the lower half of the medulla oblongata, the head enlarges and forms a prominence on the surface which has already been noticed as the tuberculum cinereum (p. 481).

The fibres which spring from the cells of the nucleus gracilis and the nucleus cuneatus and break through the neck of the posterior grey column are called the *internal arcuate fibres*. They reach the raphe on the deep or dorsal aspect of the pyramidal fasciculus and, in the median plane at the

level of the olives, where they form a very complete decussation with the corresponding fibres of the opposite side, termed the *decussation of the lemniscus* or *sensory decussation.* As soon as they reach the opposite side

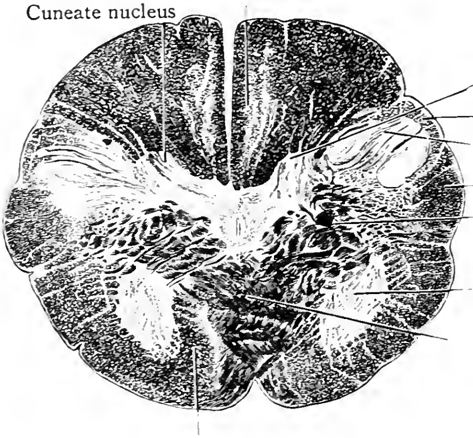

FIG. 200.—Section through the lower part of the Medulla Oblongata of the Orang.

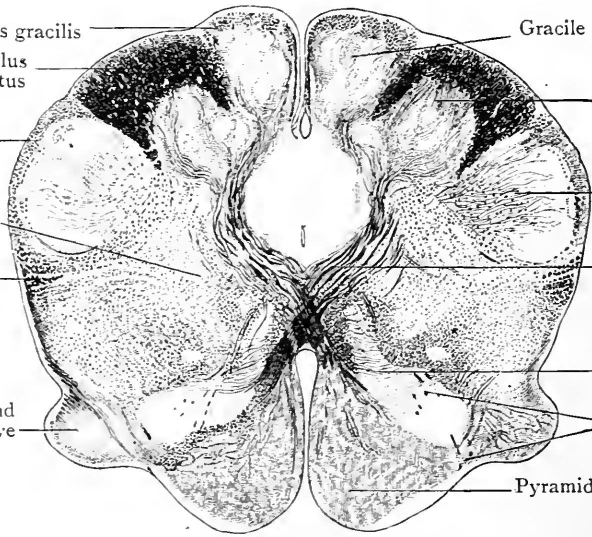

FIG. 201.—Transverse section through the lower part of the Medulla Oblongata of a full-time Fœtus, above the Decussation of the Pyramids, treated by the Weigert-Pal method. The grey matter is white, and the medullated strands of nerve fibres are black.

of the medulla oblongata the internal arcuate fibres turn upwards, and, together with the fibres of the spino-thalamic fasciculi, which are ascending from the lateral and anterior funiculi of the spinal medulla, they form a well-marked longitudinal tract called the *medial lemniscus.*

The *medial lemniscus* or *fillet* is placed close to the raphe, on the dorsal aspect of the pyramidal motor fasciculus.

The anterior column of grey matter is divided in a similar manner, by the fibres of the lateral cerebro-spinal fasciculus as it passes from the pyramid to the lateral funiculus of the opposite side of the medulla spinalis. The basal part of the divided anterior grey column remains near the central canal, but the head is displaced and forced dorso-laterally into the lateral area of the medulla oblongata, where it becomes continuous with strands of grey matter called the *nucleus ambiguus* and the *nucleus lateralis*.

Half-way up the medulla oblongata the central canal, which has been gradually approaching the dorsal surface, opens out into the cavity of the fourth ventricle, and the remains of the posterior grey columns, which surrounded it at lower levels, are spread out on the floor of the ventricle in such a manner that the portion which corresponds with the basal part of

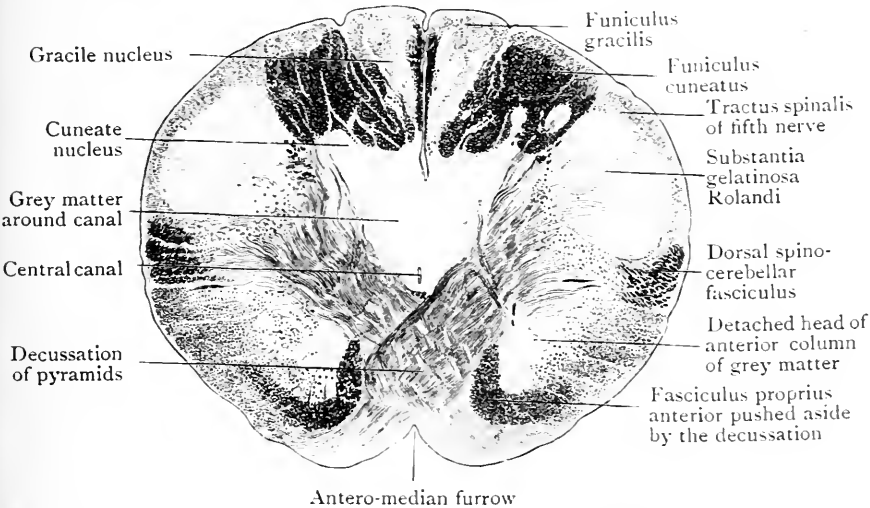

FIG. 202.—Transverse section through lower end of the Medulla Oblongata of a full-time Fœtus, treated by the Weigert-Pal method. The grey matter is therefore bleached white; whilst the medullated tracts are black.

the anterior grey column of the spinal medulla is situated close to the median plane, whilst the part which represents the base of the posterior grey column of the spinal medulla occupies a more lateral position; therefore the hypoglossal nerve, which is a motor nerve, springs from the grey matter near the median plane which is an upward prolongation of the motor or anterior grey column, and the fibres of the glosso-pharyngeal and vagus nerves, which are mainly sensory nerves, terminate in association with the more laterally situated grey matter of the medulla oblongata which is continued upwards from the base of the posterior grey column of the spinal medulla.

As the central canal opens out into the cavity of the fourth ventricle and the basal parts of the posterior grey columns are forced laterally, the ependymal epithelium of the dorsal wall of the canal is expanded into the extensive epithelial membrane, which forms the roof of the lower part of the fourth ventricle.

Every section of the upper portion of the medulla oblongata is divided into medial, lateral, and dorsal parts by the roots of the hypoglossal nerve

and the roots of the vagus and glosso-pharyngeal nerves. The medial part lies between the root fibres of the hypoglossal nerve and the median raphe. It consists mainly of white matter, but on its ventral aspect, close to the anterior median fissure, lies the *nucleus of the external arcuate fibres*, embedded amongst those fibres; and on the lateral part of the dorsal aspect of the pyramidal fasciculus, there is a tract of nerve cells which is called the *medial accessory olive*.

The nerve fibres of the medial area are longitudinal, transverse and oblique. The *longitudinal fibres* form four main strands. Ventrally they form the *pyramidal fasciculus*; immediately dorsal to the pyramidal fasciculus they constitute the medial lemniscus; behind the *lemniscus* are the *tecto-spinal fibres*, and still more dorsally, immediately subjacent to the grey matter of the floor of the fourth ventricle, is the *medial longitudinal fasciculus*. The medial lemniscus consists of the fibres of the spino-thalamic fasciculi, prolonged upwards from the lateral and anterior funiculi of the spinal medulla, and of internal arcuate fibres derived from the gracile and cuneate nuclei of the opposite side. The tecto-spinal fibres are descending from the lamina quadrigemina to the spinal medulla. The medial longitudinal fasciculus is continuous, below, with the fasciculus anterior proprius of the spinal medulla. It ascends through the medulla, pons, and mid-brain to the subthalamic region, forming intimate associations with the motor nuclei of the cerebral nerves.

The *oblique* and *transverse fibres* of the medial area are internal and external arcuate fibres.

The most striking feature in transverse sections of the upper part of the lateral area of the medulla oblongata is the *olivary nucleus*, which lies subjacent to the olivary eminence. It presents the appearance of a thick undulating layer of grey matter, folded on itself so as to enclose a space filled with white matter and open towards the median plane. It is in reality a grey lamina arranged in a purse-like manner with the open mouth directed towards the raphe. Dorsal to the olivary nucleus lies the *dorsal accessory olivary nucleus*. More dorsally there are columns of nerve cells which form the *nucleus lateralis* and the *nucleus ambiguus*, and which are continuous, below, with the head of the anterior grey column of the spinal medulla. Still more dorsally is the ventral part of the nucleus of the spinal tract of the trigeminal nerve.

The white matter of the lateral area consists of longitudinal and oblique fibres, and that portion of it which lies dorsal to the olivary nucleus is sometimes spoken of as the *formatio reticularis grisea*, because it contains a certain amount of grey matter, whilst the corresponding part of the medial area, which is practically devoid of grey matter, is called the *formatio reticularis alba*.

Some of the longitudinal white fibres of the lateral area of the medulla oblongata form definite fasciculi which associate together different grey masses. Close to the surface, below the level of the olive, and immediately dorso-lateral to the issuing fila of the hypoglossal nerve lies the *bulbo-spinal fasciculus*. On the superficial aspect of the olivary nucleus and along its dorso-lateral border is the *thalamo-olivary fasciculus*, and dorsal to the thalamo-olivary fasciculus are the ventral and the dorsal spino-cerebellar fasciculi. More medially lie the rubro-spinal fasciculus and fibres of the spino-thalamic fasciculi; the oblique fibres are internal and external arcuate fibres. Some of the internal arcuate fibres are passing between the gracile and cuneate nuclei and the restiform body of the opposite side, and some are connecting the cerebellar hemisphere of one side with the olivary nucleus of the opposite side.

The dorsal area of each half of the medulla oblongata also consists

of intermingled grey and white matter. The upward prolongation of the separated head of the posterior grey column forms the *nucleus of the spinal tract of the trigeminal nerve*, which lies partly in the dorsal and partly in the lateral area. Medial to it lie the upward prolongations of the nucleus gracilis and the nucleus cuneatus, and at a higher level the nuclei of the vestibular portion of the acoustic nerve. Medial to the nucleus gracilis, on the margin of the grey matter of the floor of the fourth ventricle, is the fasciculus solitarius, a strand of nerve fibres and nerve cells; the fibres being fibres of the glosso-pharyngeal and the vagus nerves passing to the cells of the strand which forms one of their nuclei.

The white fibres of the posterior area are longitudinal and oblique. The most important longitudinal fibres are—(1) the fibres of the spinal root of the trigeminal nerve which descend, close to the surface, and superficial

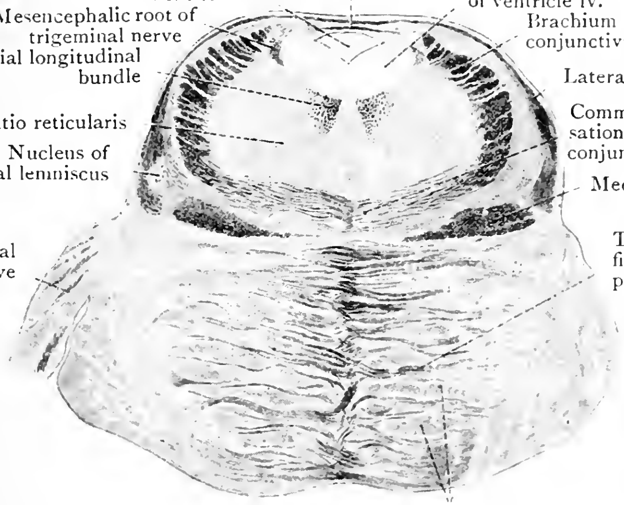

FIG. 203.—Transverse section through the upper part of the Pons of the Orang.

to the nucleus, which is formed by the upward prolongation of the head of the posterior column of grey matter; and (2) the fibres of the fasciculus solitarius (see above). The oblique fibres consist of fibres of the restiform body, fibres passing from the nucleus gracilis and nucleus cuneatus, and of fibres passing to the olivary nucleus of the opposite side.

Internal Structure of the Pons.—When transverse sections are made through the pons, it is seen to consist of two well-defined parts, viz., a ventral and a dorsal. Broadly speaking, the *ventral part*, *pars basalis*, corresponds to the pyramidal parts of the medulla oblongata, and the basal parts of the pedunculi cerebri; whilst the *dorsal part* corresponds to the formatio reticularis of the medulla oblongata and the tegmental parts of the pedunculi cerebri.

The *basilar part of the pons* is the larger of the two subdivisions. It is composed of a large number of transverse bundles of fibres, through the midst of which coarse longitudinal bundles of fibres proceed down-

wards from the bases of the pedunculi cerebri; some of the longitudinal fibres are cerebro-spinal fibres, passing to the medulla oblongata where they form the bundles of the pyramids. Others are cerebro-pontine fibres; they terminate round the cells of the *nuclei pontis*, which are the small masses of grey matter which occupy the interstices between the transverse and longitudinal bundles of fibres. Of the transverse fibres two distinct sets may be recognised, viz., the superficial transverse fibres, through the midst of which the bundles of cerebro-spinal fibres are prolonged, and a deeper set termed the *corpus trapezoidum*. The *superficial transverse fibres* traverse the entire thickness of the ventral part of the pons, and on each side, pass into the corresponding brachium pontis. The *trapezial fibres* lie posterior to the cerebro-spinal bundles in the boundary area between the dorsal and ventral parts of the pons, but encroach considerably into the ground of the former. They are seen only in the lower part of the pons, and they pass into the lateral lemniscus. They take origin in the terminal nucleus of the cochlear division of the acoustic nerve.

The *dorsal or tegmental part of the pons* is, for the most part, formed of a prolongation upwards of the formatio reticularis of the medulla. Superiorly, it is carried into the tegmental parts of the pedunculi cerebri. It is divided into two halves by a median raphe, which is continuous, below, with the raphe of the medulla oblongata, and, above, with the raphe of the tegmental part of the mesencephalon, whilst over its dorsal surface is spread a thick layer of grey matter which belongs to the upper part of the floor of the fourth ventricle. In transverse sections through the upper part of the pons a dark spot in the lateral part of the floor indicates the position of a small mass of pigmented cells called the *substantia ferruginea*. It underlies the locus cœruleus.

Four strands of longitudinal fibres are seen on each side in transverse sections through the dorsal part of the pons. These are—(1) the medial lemniscus, (2) the lateral lemniscus, (3) the medial longitudinal bundle, and (4) the brachium conjunctivum.

The *medial lemniscus* assumes, in the pons, a ribbon-shaped form. It is placed between the ventral part of the pons and the formatio reticularis of the dorsal part.

The *lateral lemniscus*, largely composed of fibres derived directly or indirectly from the corpus trapezoidum, is seen in the upper part of the pons. It sweeps round the lateral side of the brachium conjunctivum to gain the surface.

The *medial longitudinal bundle* is much more distinct than it is in the medulla oblongata. It has separated itself more completely from the longitudinal fibres of the formatio reticularis, and it is now seen, close to the median plane, immediately subjacent to the grey matter of the floor of the fourth ventricle.

The *brachium conjunctivum*, in transverse sections, presents a semilunar outline. It occupies a lateral position in the dorsal part of the pons, and gradually sinks deeply into its substance, although it does not become completely submerged until it reaches the mesencephalon.

The *superior olive* is a small isolated clump of grey matter which is embedded in the dorsal part of the pons in the path of the fibres of the corpus trapezoidum.

CRANIAL TOPOGRAPHY

After the gyri and sulci of the hemispheres and the various parts of the mid-brain and the hind-brain have been carefully studied the dissectors

should obtain a skull which has been divided in the median sagittal plane, and should study the relationships of the various gyri and sulci of the

supero-lateral surface of each hemisphere to the bones of the cranial vault, and to the grooves for the main branches of the middle meningeal arteries,

which are situated on the inner surface of the skull wall. They should note especially, in relation to the bones and the arterial grooves, the situations of the posterior horizontal limb of the lateral fissure, the central sulcus and the occipital pole of each hemisphere, because :—(1) in the lower lip of the posterior horizontal limb of the lateral fissure lies the acoustic area ; (2) the anterior central gyrus, which lies in front of the central sulcus, is the general motor area of the brain ; (3) the posterior central gyrus, which lies behind the central sulcus, is the general sensory area ; and (4) the occipital pole is in the region of the visual area (Figs. 153, 204).

The anterior branch of the middle meningeal artery lies, as a rule, over the region of the anterior central gyrus (Fig. 204), and the posterior branch, which is, however, more irregular in position, frequently runs along the ine of the first temporal gyrus, which is immediately below the posterior horizontal limb of the lateral fissure, and consequently it crosses or lies close to the acoustic area (Fig. 204).

The general positions of the sulci and gyri are shown in Figs. 135, 152, and in Fig. 38, which is a reproduction of a radiograph of a head in which metallic rods and pieces of metallic paste had been introduced, other important areas have also been made visible.

The exact positions of the various cerebral sulci vary, to a certain extent, in heads of different shapes and sizes, but a sufficiently accurate estimation, for practical purposes, can be made on any head or skull by the use of a few easily remembered points and lines (Fig. 204). They are :—

(1) A base line extending from the lower margin of the orbit to the upper border of the external acoustic meatus (5-5, black, Fig. 204).

(2) A line, 30 mm. long, extending backwards from the lower end of the zygomatic process of the frontal bone, *parallel with the base line* (6, black, Fig. 204).

(3) A line, 10 mm. long, projected upwards at right angles to (2) from its posterior end (8, black, Fig. 204). The upper end of (3) marks the "Sylvian point," which lies at or near the pterion, and it marks the position where the lateral end of the stem of the lateral fissure divides into its three terminal branches (9, black, Fig. 204).

(4) A line projected from the lower end of the zygomatic process of the frontal bone, *through the "Sylvian point,"* to the median plane (2-2, black, Fig. 204). This line usually strikes the median plane a short distance in front of the lambda ; the first 75 mm. (three inches) of it, behind the "Sylvian point," mark the position of the straight part of the posterior horizontal limb of the lateral fissure, and the last 18 mm. (about three-quarters of an inch) indicate the position of the upper and lateral part of the parieto-occipital fissure.

(5) A line marking the general position of the central sulcus. It commences 25 mm. (one inch) behind the "Sylvian point," immediately above the lateral fissure, and extends upwards and backwards to a point in the median plane situated 12.5 mm. (half an inch) behind the central point on a line extending from the root of the nose (nasion) to the external occipital protuberance (inion) (1, blue, Fig. 204).

The occipital pole of the hemisphere lies immediately above and lateral to the external occipital protuberance.

THE AUDITORY APPARATUS.

THE organ of hearing admits of a very natural subdivision into three parts, viz., the external, the middle, and the internal ear.

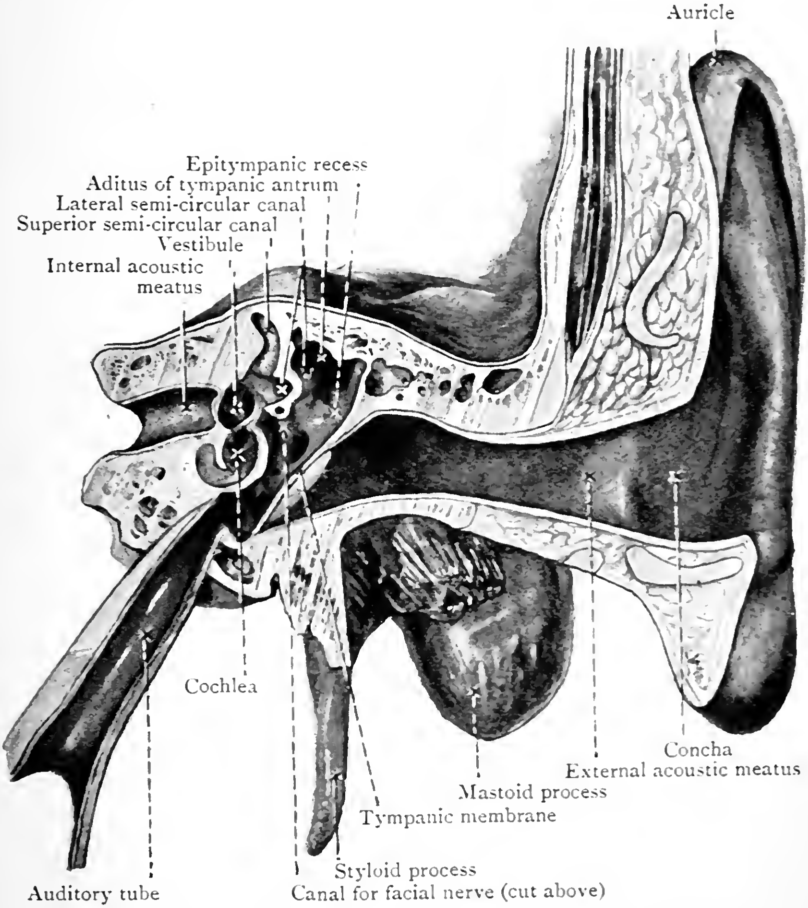

FIG. 205.—The parts of the Ear (semi-diagrammatic). The purple colour indicates the mucous lining of the tympanic cavity, which is continuous, through the auditory tube, with the mucous lining of the pharynx, and, through the aditus, with the mucous lining of the tympanic antrum.

The *external ear* consists of the auricle and the external acoustic meatus. The auricle collects the waves of sound, and is, comparatively speaking, of subsidiary importance in man, although it is of considerable service in

some of the lower animals. The external acoustic meatus is a passage leading inwards, from the bottom of the concha of the auricle, to the membrana tympani, which separates the external ear from the middle ear. The *middle ear* is a narrow chamber termed the *tympanic cavity.* It is interposed between the external acoustic passage and the internal ear or labyrinth, and the main part of its lateral wall is formed by the membrana tympani. Stretching across the cavity of the tympanum, from its lateral to its medial wall, there is a chain of three small bones, called the auditory ossicles. The *internal ear*, or labyrinth, is the most essential part of the organ. It consists of a complicated system of cavities situated in the densest part of the petrous portion of the temporal bone. The cavities contain fluid called perilymph, and also a membranous counterpart of the bony chambers, called the membranous labyrinth. Within the latter there is fluid termed endolymph.

External Ear.

Dissection.—The dissection of the ear should be conducted differently on opposite sides.

On one side remove the lateral pterygoid lamina and the remains of the external and internal pterygoid muscles, if that has not been done already. Then clear away the tensor veli palatini muscle and expose the lateral surface of the auditory tube. Dissect on the postero-medial aspect of the tube and expose the levator veli palatini muscle, from the lateral side. Follow the muscle downwards and medially, below the lower orifice of the tube, into the soft palate. Then detach the auditory tube from the posterior border of the medial pterygoid lamina; cut the levator veli palatini at the point where it enters the soft palate, and separate the cartilaginous part of the auditory tube from any parts of the wall of the pharynx which may still be connected with it. When that has been done turn to the temporal bone; place the saw at right angles to the external surface of the squamous part and saw through the bone, along the line of the petro-tympanic fissure, to the posterior border of the spine of the sphenoid. Turn next to the medial surface and saw through the body of the sphenoid at the level of the anterior boundary of the foramen lacerum; then, with the aid of the chisel and bone forceps, detach the posterior border of the great wing of the sphenoid from the anterior border of the petrous part of the temporal bone. When the dissection is properly done the greater part of the temporal bone is removed from the remainder of the skull, with the cartilaginous part of the auditory tube attached to the anterior margin of its petrous portion, and a small part of the body of the sphenoid bone attached to its apex. The anterior wall of the mandibular fossa was separated by the first saw-cut, but the posterior wall is still present, with the cartilaginous part of the auditory tube attached to its medial

end and the cartilaginous part of the external acoustic meatus to its lateral border. The dissector should now cut away the tragus of the auricle, to expose the orifice of the external meatus which lies at the bottom of the concha; then, with knife or scissors, he must remove the anterior wall of the cartilaginous part of the external meatus. Next pass a probe into the bony part of the meatus to gauge its length, and, whilst the probe is kept in position as a guide, cut away the anterior wall of the bony part of the meatus, taking care not to injure the tympanic membrane which closes the medial end of the meatus. When the dissection is completed the boundaries of the meatus and the lateral surface of the tympanic membrane should be examined.

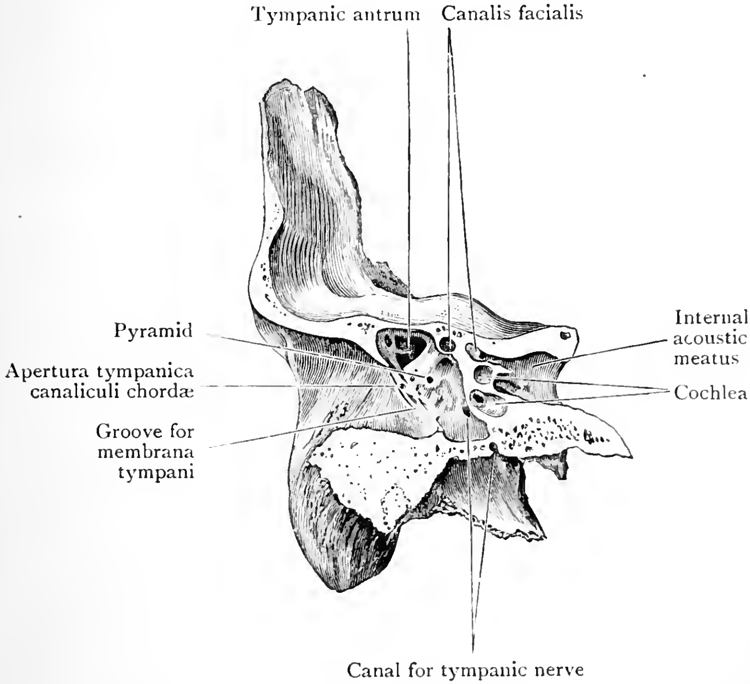

FIG. 206.—Frontal section of the Right Temporal Bone passing through the external and the internal acoustic meatuses.

Meatus Acusticus Externus.—The external acoustic meatus runs forwards and medially, from its lateral orifice to its medial boundary, and, during its course, it forms a slight curve with the convexity upwards. Its total length, measured from the bottom of the concha to the tympanic membrane, is about 24 mm., of which 8 mm. corresponds with the cartilaginous part, and 16 mm. with the bony part of the canal; but, as the membrana tympani is placed obliquely, the anterior wall and

the floor are longer than the posterior wall and the roof, respectively. Moreover, the diameter of the canal is not uniform. It is narrowest at the isthmus, which lies about 5 mm. from the tympanic membrane; and its vertical diameter is greatest at the lateral end, whilst its antero-posterior diameter is greatest at its medial end. These facts must be borne in mind during the removal of foreign bodies which have made their way into the canal. As the tube passes from the surface, medially, it describes a gentle sigmoid curve, but its general direction is towards the median plane with a

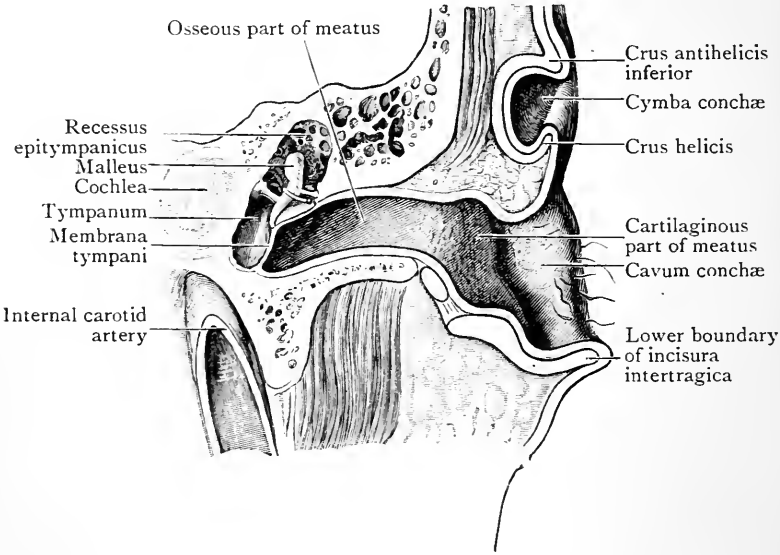

FIG. 207.—Vertical transverse section through the Right Ear: anterior half of section viewed from behind. (Howden.)

slight inclination forwards. The skin lining the cartilaginous portion is abundantly furnished with ceruminous glands and is provided also with laterally directed hairs, which tend to prevent the entrance of dust. The cutaneous lining of the osseous part, which is thin and tightly adherent to the subjacent periosteum, is destitute of hairs, and glands are for the most part absent. The cutaneous lining of the meatus is continued, in the form of an exceedingly delicate layer, over the lateral surface of the membrana tympani.

When the direction, the length, and the diameters of the external meatus have been noted, the dissectors should examine the lateral surface of the tympanic membrane.

Membrana Tympani.—The slope of the tympanic membrane has already been referred to. It slopes very obliquely downwards, forwards and medially, and its lateral surface is deeply concave. The deepest point of the concavity is the *umbo*,[1] which corresponds with the lower end of a bar of bone, *the handle of the malleus*, which is embedded in the membrane and can be seen through the thin layer of tissue covering it. The handle of the malleus extends upwards, and slightly backwards, from the umbo towards the roof of the meatus; and a short distance from the upper margin of the membrane it becomes continuous with a small laterally directed process, the *lateral process of the malleus*, which bulges the membrane towards the meatus. Above the lateral process of the malleus there is a portion of the membrane which is less tense than the remainder. It is the *membrana flaccida* (Shrapnell's membrane). It is bounded anteriorly and posteriorly by relatively thickened borders, called the *anterior* and *posterior malleolar folds*. The whole of the peripheral margin of the membrane, except that which corresponds with the membrana flaccida, is lodged in a ring-like sulcus of bone, the *sulcus tympanicus*, which is formed by the tympanic element of the temporal bone.

Dissection.—After the examination of the external meatus is completed the dissector must secure the tensor tympani muscle, which springs from the petrous part of the temporal bone, close to the apex and above the level of the cartilaginous part of the auditory tube. Having secured it, he must trace it laterally, above the auditory tube, to the point where it passes into the bony canal through which it enters the tympanum. Then he must cut away the antero-lateral wall of the cartilaginous part of the auditory tube, from the pharyngeal orifice to the upper extremity, and pass a probe through the bony part of the tube into the tympanum. He should next turn to the anterior surface of the petrous part of the temporal bone and, with chisel and bone forceps, carefully remove the tegmen tympani and expose the tympanic cavity from above. The dissection must be carried forwards into the auditory tube and backwards into the tympanic antrum. As the dissection is carried forwards a narrow margin of bone must be left along the anterior border of the tympanic membrane, and care must be taken to avoid injury to the tendon of the tensor tympani, which emerges from the extremity of its bony canal, near the medial wall of the tympanum, and crosses the cavity to be inserted into the malleus. The chorda tympani nerve, which

[1] The term "umbo" refers to a prominence and would be more properly used in association with the convexity on the inner side of the membrana tympani than with the concavity on its outer aspect.

passes forwards, close to the tympanic membrane and above the tendon of the tensor tympani, must also be preserved, if possible.

Middle Ear, Tympanic Antrum, and Auditory Tube

Cavum Tympani or Middle Ear.—The tympanic cavity is a small chamber, containing air, which is placed between the bottom of the meatus externus and the internal ear or labyrinth (Fig. 209). Posteriorly, it communicates, by a relatively large orifice, called the *aditus*, with the tympanic antrum and the mastoid air-cells; whilst, anteriorly, the auditory tube opens into it and puts it into connection with the cavity of the pharynx. It contains the chain of auditory ossicles, which crosses from its lateral to its medial wall; and it is lined with delicate mucous membrane.

The vertical depth and the antero-posterior length of the tympanic cavity are each about 12.5 mm. (*half an inch*). Its width, from side to side, is about 4.5 mm. (*a sixth of an inch*); and, as both its lateral and medial walls bulge into the cavity, its width in the centre is still further reduced. The tympanic cavity consists of—(1) an upper part, which extends upwards beyond the level of the membrana tympani, and to which the term *recessus epitympanicus* is applied (Figs. 207, 208); and (2) the *tympanum proper*, which lies immediately to the medial side of the membrana tympani. The tympanic cavity presents for examination a roof and a floor, and four walls, viz., anterior, posterior, lateral, and medial.

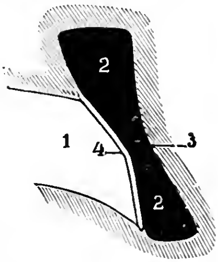

Fig. 208.—Schematic vertical section through the Tympanum. (From Testut.)

1. External meatus.
2. Tympanic cavity (the upper "2" is in the recessus epitympanicus).
3. Promontory on medial wall.
4. Membrana tympani.

The *roof* is composed of a thin plate of bone, termed the *tegmen tympani*, which separates the cavity from the middle fossa of the cranium. In chronic inflammatory conditions of the middle ear, an extension of the inflammatory process, through the tegmen, to the meninges of the brain is always to be feared.

The *floor* or *jugular wall* is narrow, and it also is formed by a thin osseous lamina, which is interposed between the

tympanum and the jugular fossa. It separates the tympanum from the bulb of the internal jugular vein, and an extension of an inflammatory condition of the middle ear, through the bone to the vein, may lead to thrombosis (clotting).

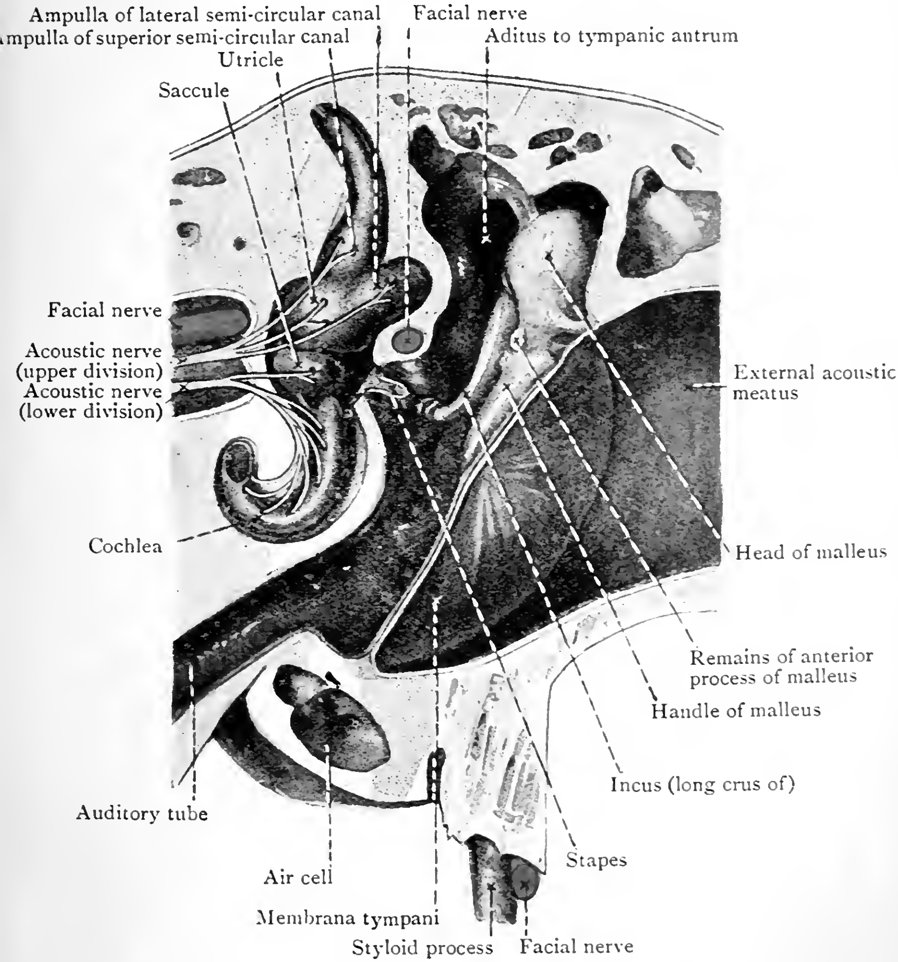

FIG. 209.—The Tympanic Cavity and adjacent parts (semi-diagrammatic).

The *posterior* or *mastoid wall* presents, in its upper part, the opening or *aditus* which leads from the recessus epitympanicus into the tympanic antrum, and below that, close to the medial wall, is a small hollow conical projection termed the *pyramid* (Fig. 213). The pyramid is perforated on its summit, and the aperture leads into a canal which curves backwards and then downwards until it opens into the lower

part of the last stage of the canalis facialis. The curved canal of the pyramid lodges the stapedius muscle, the delicate tendon of which enters the tympanic cavity through the aperture on the summit of the pyramid. Lateral to the pyramid is the aperture on the posterior wall called the *apertura tympanica canaliculi chordæ* through which the chorda tympani nerve enters the tympanum.

The *anterior wall* is narrow, because the medial and lateral walls converge anteriorly. The upper part of the anterior wall

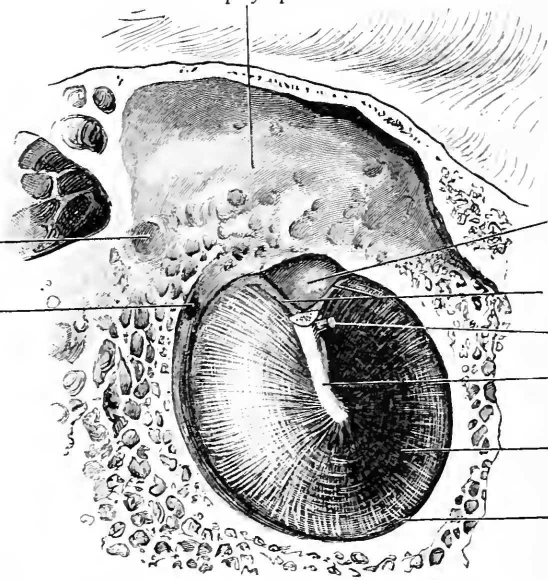

FIG. 210.—Left Membrana Tympani and Recessus Epitympanicus viewed from within. The neck and head of the malleus have been removed to show the membrana flaccida. (Howden.)

is occupied by the opening of the tensor tympani canal; the intermediate part by the tympanic orifice of the auditory tube; and the lowest part is a lamina of bone which separates the tympanic cavity from the carotid canal. The tympanic end of the septum between the auditory tube and the tensor tympani canal is called the *processus cochleariformis*; it serves as a pulley round which the tendon of the tensor tympani muscle turns abruptly, in a lateral direction, towards the malleus.

On the *medial wall*, which intervenes between the tympanum and the labyrinth, there are eminences, depressions,

and apertures which require notice. The anterior, and larger, part of the wall bulges laterally, into the cavity (Figs. 209, 213), and forms a very evident elevation, termed the *promontory*. Above the posterior part of the promontory there is a depression called the fossa of the fenestra vestibuli; and at the bottom of the fossa is an oval aperture called the *fenestra vestibuli* (Fig. 213). The long axis of the fenestra is directed antero-posteriorly, and, in the macerated bone, the aperture opens into the vestibular part of the labyrinth,

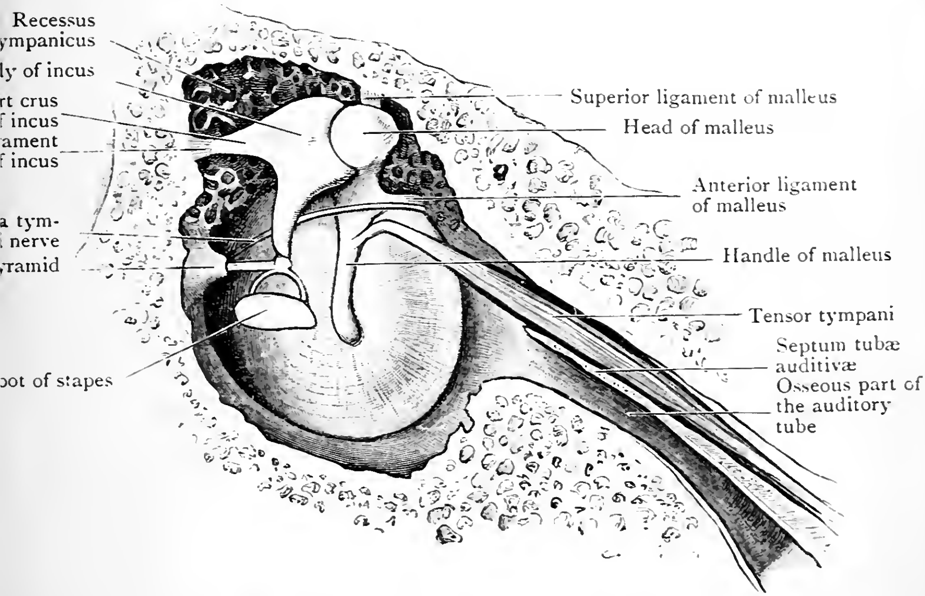

FIG. 211.—Left Membrana Tympani and Chain of Tympanic Ossicles seen from the medial aspect. (Howden.)

but, in the recent state, it is closed by the footpiece of the stapes (Fig. 209), the most medial of the auditory ossicles, which is implanted in the fenestra. The pyramid, on the posterior wall, is immediately posterior to the fenestra vestibuli. Above the fenestra vestibuli, in the angle formed by the meeting of the roof and medial wall of the tympanum, and therefore in the recessus epitympanicus, is an antero-posterior ridge. It is produced by the canalis facialis bulging into the tympanum (Fig. 213). The wall of the canal is very thin, and allows the white facial nerve, which is contained within the canal, to be readily seen. Below and behind the promontory is the fossula fenestræ cochleæ,

and at the bottom of the fossa there is an aperture called the *fenestra cochleæ*; in the macerated bone the aperture leads into the cavity of the cochlea, but, in the recent state, it is closed by a membrane called the *secondary membrane of the tympanum.*

The *lateral wall* of the tympanic cavity is formed, for the most part, by the membrana tympani, but, above the tympanic membrane, the lateral wall of the recessus epitympanicus is formed by a portion of the squamous part of the temporal bone (Figs. 209, 210).

Membrana Tympani.—The membrana tympani is an elliptical disc of membrane which is stretched across the

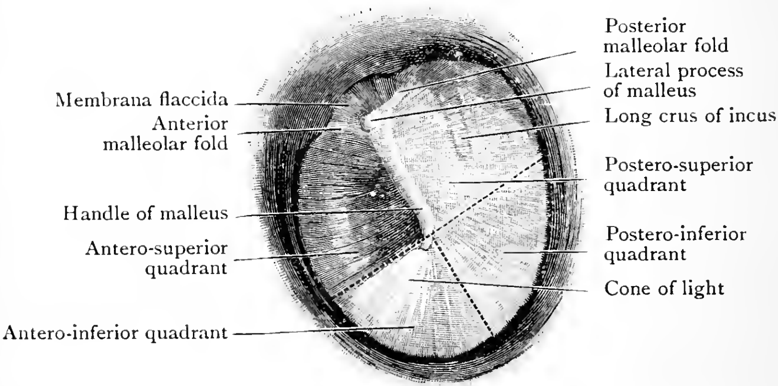

FIG. 212.—Left Tympanic Membrane as viewed from the external meatus during an otoscopic examination. The dotted lines indicate the manner in which the tympanic membrane is subdivided arbitrarily into four areas or quadrants. (Howden.)

medial end of the meatus acusticus externus, and it forms the greater part of the lateral wall of the tympanum. It is placed very obliquely; its lower and its anterior borders both inclining medially.

The mode of attachment of the membrane deserves some attention. At the medial end of the meatus a ring-like ridge of bone, very distinctly grooved, forms a frame in which the membrane is set (Fig. 210). But the ridge is deficient above, where its extremities are separated by a deep notch called the *incisura tympanica.* The notch is occupied by a portion of the membrane which is not so dense in its texture (seeing that the fibrous layer is absent), and not so tightly stretched as the remainder; consequently it receives the name of the

membrana flaccida (Shrapnell's membrane). The circular groove in the bony ridge is called the *sulcus tympanicus*. The edge of that part of the membrane which is fixed in the sulcus tympanicus is thickened, and at the incisura tympanica, the thickened part, it is carried down, anterior and posterior to the membrana flaccida, in the form of two bands, called respectively the *anterior* and *posterior malleolar folds*.

The membrana tympani is composed of three layers—viz., a lateral cuticular layer, an intermediate fibrous lamina, and

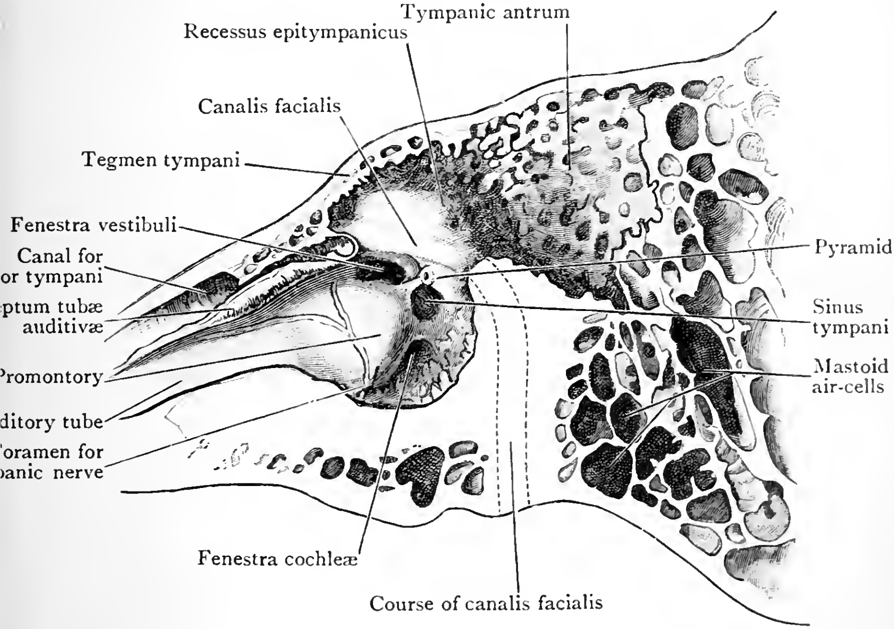

FIG. 213.—Vertical section through the Left Ear: postero-medial half of section viewed from the front. (Howden.)

a medial mucous layer. The handle of the malleus is intimately connected with the fibrous layer, and is covered medially by the mucous layer. It draws the membrane towards the tympanic cavity, and is the cause of the concavity on the lateral surface. The deepest point of that concavity corresponds with the flattened extremity of the handle of the malleus, and is termed the *umbo*.

When the living ear is examined, with a speculum, the surface of the membrane appears highly polished, and a cone of light extends downwards and forwards from the tip of the handle of the malleus. A pair of striæ (Prussak's striæ), which correspond to the anterior and posterior malleolar folds, extend from the processus lateralis of the malleus to the margins

of the incisura tympanica, and thus map out the membrana flaccida. The long crus of the incus can be faintly seen through the membrana tympani, parallel with and posterior to the handle of the malleus.

Antrum Tympanicum.—The tympanic antrum is a recess or air-chamber, in the temporal bone. It lies immediately behind the epitympanic portion of the tympanic cavity and, in the adult, it is 14 mm. (*about half an inch*) from the surface of the skull, medial to the suprameatal triangle. In the child it is much more superficial.

The cavity of the tympanic antrum is lined with mucous membrane which is continuous, anteriorly, through a relatively wide aperture called the *aditus*, with the mucous membrane of the tympanic cavity, and it is also continuous, posteriorly and below, with the mucous membrane of the air-cells in the mastoid portion of the temporal bone.

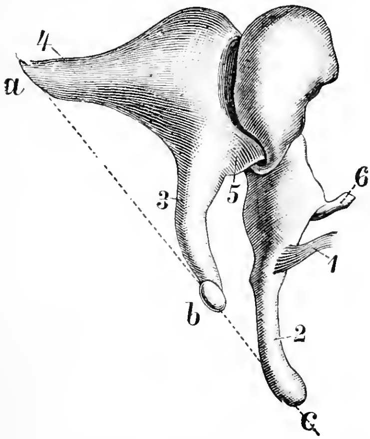

FIG. 214.—Left Malleus and Incus. (After Helmholtz.)

1. Tendon of tensor tympani.
2. Handle of the malleus.
3. Long crus of the incus.
4. Short crus of the incus.
5. Incus.
6. Anterior process of the malleus. The straight line *a b c* connects the extremities of the two crura of the incus with the extremity of the manubrium of the malleus.

The *roof* of the tympanic antrum is formed by a thin plate of the petrous part of the temporal bone, called the *tegmen tympani*. It separates the tympanic antrum from the cavity of the middle fossa of the skull and from the membranes covering the inferior surface of the temporal lobe of the brain. The *lateral wall* is formed by that portion of the squamous part of the temporal bone which lies immediately above and behind the aperture of the external acoustic meatus. The *posterior wall* and the *floor* are formed by the mastoid portion of the temporal bone, and it is through apertures in those boundaries that the cavity of the tympanic antrum communicates with the mastoid air-cells. On the *medial wall*, which is formed by the petrous part of the temporal bone, is a horizontal bulging, caused by the lateral semicircular canal of the internal ear; the bulging extends forwards into the aditus (Fig. 205). Immediately anterior to the medial margin

of the aditus the canalis facialis descends along the posterior border of the medial wall of the tympanum.

The antero-posterior diameter of the tympanic antrum is about 14 mm., the vertical diameter, about 9 mm., and the transverse diameter, about 7 mm.

Tympanic Mucous Membrane.—The tympanum is lined, throughout, with a thin mucous membrane which is continuous with the mucous membrane of the pharynx, through the auditory tube. As already mentioned, it forms the medial layer of the membrana tympani, and it is prolonged posteriorly into the tympanic antrum and mastoid air-cells. It covers the ossicles also, and it invests the tendons of the stapedius and tensor tympani muscles.

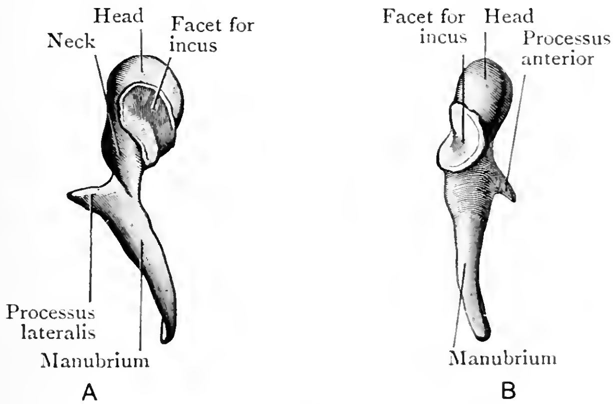

FIG. 215.—The Left Malleus. (Howden.)

A. Posterior aspect. B. Medial aspect.

Ossicula Auditus.—The auditory ossicles are the malleus, the incus, and the stapes.

The *malleus* presents a head, a neck, a manubrium, and two processes termed the processus lateralis and the processus anterior. The *head* is large and rounded. It is directed upwards, and lies above the level of the membrana tympani, in the recessus epitympanicus, close to the roof and the lateral wall of the tympanum (Figs. 209, 211). On its posterior aspect there is a notch-like articular surface, for articulation with the body of the incus. The *manubrium* is attached to the fibrous layer of the membrana tympani. The *processus lateralis* (O.T. *brevis*) is a stunted projection which springs from the root of the manubrium. It is directed laterally, and abuts against the membrana tympani immediately below the membrana flaccida. The *processus anterior* (O.T. *gracilis*) is a slender spicule of bone which passes forwards and downwards into the petro-tympanic fissure. It almost invariably breaks when the malleus is detached from the adult skull, but it can be easily preserved in the skull of an infant.

The *incus* is shaped somewhat like a præmolar tooth in which the roots are very divergent. It presents a body and a long and a short crus. The

body is provided with an articular surface, which looks forwards and articulates with the head of the malleus. The *short crus* is directed backwards, and its extremity is attached, by ligaments, to the posterior wall of the tympanum, below the opening into the tympanic antrum. The *long crus* proceeds downwards and medially, in a direction nearly parallel

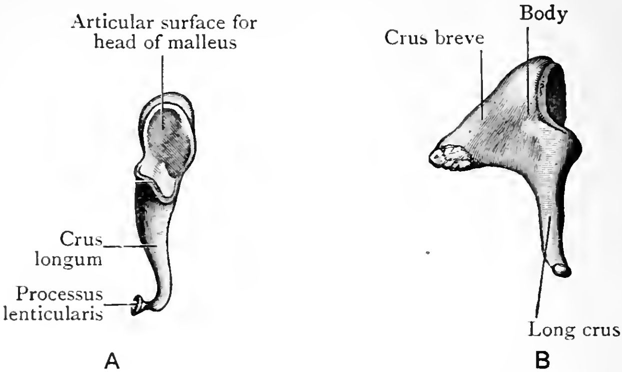

FIG. 216.—The Left Incus. (Howden.)

A. Anterior aspect. B. Medial aspect.

to that of the manubrium of the malleus, but more medial, and on a plane posterior to the manubrium. On its inferior extremity, which is bent medially, there is a small knob of bone, called the *processus lenticularis*, which articulates with the head of the stapes.

The malleus and incus move together on an axis which is formed by the processus anterior of the malleus and the crus breve of the incus. The articular surfaces of the two bones are provided with peculiar catch-teeth which interlock when the bones are performing their ordinary movements. When, however, force is applied to the medial surface of the membrana tympani, as, for instance, when the tympanum is inflated through the auditory tube, the incudo-malleolar joint gapes and the malleus moves by itself. Traction upon the attachments of the stapes, through the incus, is thus avoided.

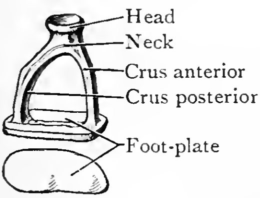

FIG. 217.—Left Stapes. (Howden.)

The *stapes* is shaped like a stirrup, and presents a head or lateral extremity separated by a slightly constricted *neck* from two crura which join a medial plate called the basis stapedis. The *head* is excavated by an articular cup for the processus lenticularis of the incus. The *crura* are grooved longitudinally on their concave sides (sulcus stapedis). The posterior crus is more sharply curved than the anterior crus. The *base* fits into the fenestra vestibuli and corresponds in its outline with that aperture. Its lower border is straight, whilst its upper border is curved.

Ligaments of the Auditory Ossicles.—In addition to the delicate articular capsules, which surround the joints between the auditory ossicles, there are certain bands which connect the bones to the walls of the tympanum and serve to restrain their movements.

In connection with the malleus there are—(1) an *anterior ligament*,

which passes forwards, from the root of the processus anterior, to the anterior wall of the tympanum in the neighbourhood of the petro-tympanic fissure; (2) a *lateral ligament*, which extends from its lateral process to the margin of the incisura tympanica; and (3) a *superior ligament*, which connects the head with the roof of the tympanum.

The *ligament of the incus* binds the extremity of its short crus to the posterior wall of the tympanum, whilst the *annular ligament of the stapes* connects the margin of its base to the circumference of the fenestra vestibuli.

Tympanic Muscles.—Two muscles are associated with the tympanum, viz., the stapedius and the tensor tympani.

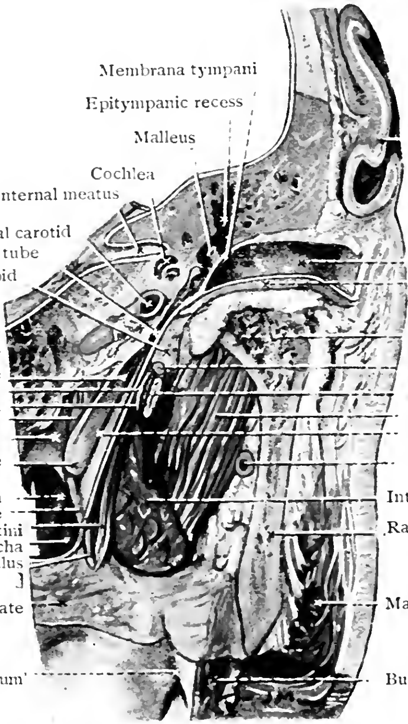

FIG. 218.—Oblique section of a part of the Head showing the relations of the Auditory Tube.

The *stapedius* occupies the interior of the pyramid and the canal which curves downwards from it. The delicate tendon of the stapedius enters the tympanum, through the aperture on the summit of the pyramid, and is inserted into the posterior aspect of the neck of the stapes. The stapedius muscle is supplied by a branch from the *facial nerve*.

The *tensor tympani* arises from the upper part of the cartilage of the auditory tube and from the contiguous parts of the great wing of the sphenoid and the petrous part of the temporal

bone. From its origin it passes backwards and laterally, above the osseous part of the auditory tube. In the tympanic cavity the tendon turns at right angles, round the extremity of the processus cochleariformis (p. 512), and passes laterally, towards the lateral wall of the tympanum, to its insertion into the upper part of the medial surface of the manubrium of the malleus. The tensor tympani receives its nerve of supply through the *otic ganglion* from the mandibular division of the trigeminal nerve. The name of the muscle indicates its action.

Chorda Tympani Nerve.—The chorda tympani, which traverses the tympanic cavity in close relation to the upper part of the membrana tympani, is described on p. 182.

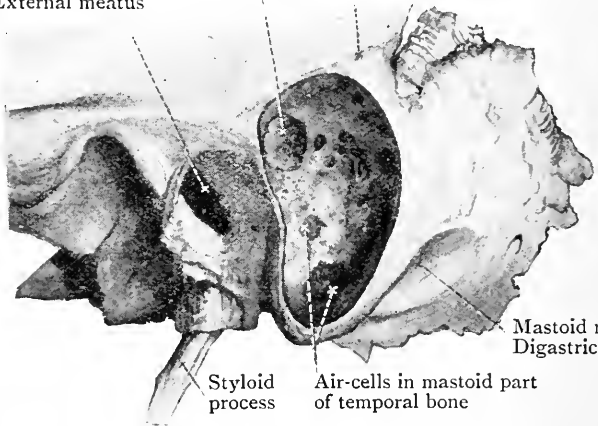

FIG. 219.—Dissection of the Tympanic Antrum and the mastoid part of the temporal bone from the outer side.

Tympanic Plexus.—This has been described previously on p. 220.

Tuba Auditiva (O.T. **Eustachian**).—The auditory tube is the passage which places the tympanic cavity in communication with the pharynx. Through it air reaches the tympanic cavity and antrum and the mastoid cells. It consists of an osseous and a cartilaginous portion. The *osseous portion* is about 12.5 mm. (*half an inch*) in length. It is widest at its entrance into the tympanum, and narrowest at its other end. The *cartilaginous portion* is about an inch in length, and has been already described on p. 298.

Dissection : **Second Method.—On the opposite side the bony part of the external meatus, the tympanic antrum, and the**

tympanic cavity should be approached from the postero-lateral aspect. The dissection of the bone should be carried out after the manner adopted by the surgeon when operating for the cure of extensive mastoid and middle ear disease, but, to facilitate the dissection, and to gain better access to the bone, the auricle may be removed by cutting through the cartilaginous part of the external meatus.

After the auricle has been cut away take all the soft parts, including the periosteum, from the outer surface of the mastoid part of the temporal bone, and identify—(1) the supra-meatal triangle and the supra-meatal spine, which lie at the junction of the superior with the posterior border of the bony part of the external meatus, and (2) the temporal line, which passes, backwards and upwards, above the supra-meatal triangle. The

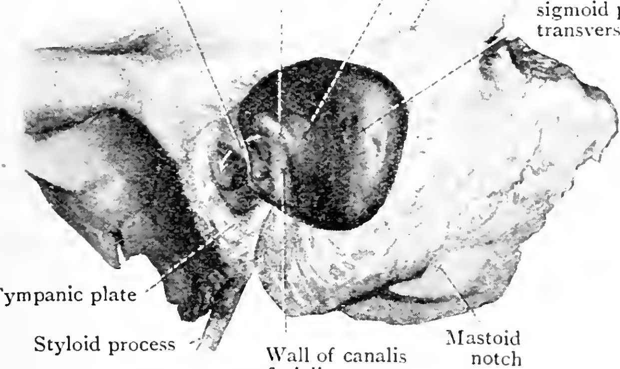

FIG. 220.—Dissection of the Tympanic Antrum and the petro-mastoid part of the temporal bone from the outer side. The arrow is passing through the aditus from the tympanic antrum into the tympanic cavity.

objects of the first stage of the dissection are—(1) the removal of the outer compact layer of bone; (2) the opening up of the spongy tissue of the mastoid part of the temporal bone, and the exposure of the mastoid air-cells and the cavity of the tympanic antrum, whilst, at the same time, injury to the posterior wall of the bony part of the external meatus and to the sigmoid part of the transverse sinus, which lies in a groove on the inner aspect of the posterior part of the mastoid portion of the temporal bone, is avoided. The tympanic antrum lies at the level of the supra-meatal triangle, that is, above and posterior to the external meatus, and about 14 mm. (*a little more than half an inch*) from the superficial surface of the temporal bone. The dissection should be commenced in the supra-meatal triangle, and should be carried, forwards and medially, into the bone, parallel with the posterior wall of the external meatus, until the tympanic antrum is opened into. After the tympanic antrum has been identified, the spongy tissue of the anterior part of the mastoid area must be gradually removed till the more medially situated

and more compact bone is exposed. When that stage of the dissection is completed, the dissector should note the following points :—(1) In the anterior boundary of the exposed area is the compact posterior wall of the bony part of the external meatus. (2) Posteriorly is a broad projecting ridge indicating the position of the groove which lodges the sigmoid part of the transverse sinus. (3) At the upper and deeper part of the area are the medial wall of the tympanic antrum and the aditus leading into the tympanic cavity. (4) The intervening area is occupied by the remains of the mastoid air-cells, which may extend downwards to the tip of the mastoid process. They are continuous above with the cavity of the tympanic antrum. (5) On the medial wall of the aditus and the anterior part of the medial wall of the tympanic antrum is a horizontal ridge which

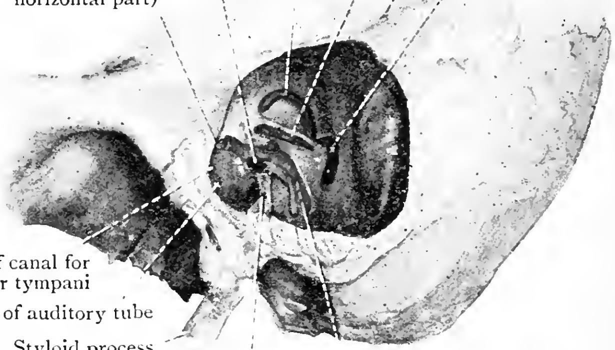

FIG. 221.—Dissection of the Tympanic Cavity and the semicircular canals from the outer side.

indicates the position of the lateral semicircular canal of the labyrinth, and, below it, on the medial wall of the mouth of the aditus, is a vertical ridge indicating the position of the canalis facialis, which lodges the important facial nerve.

The next stage of the dissection consists in the removal of the posterior wall of the external meatus, and the exposure of the lateral surface of the tympanic membrane (p. 514). After the tympanic membrane has been examined, a seeker should be passed through the aditus into the tympanic cavity, and its handle should be allowed to rest on the lower part of the exposed area ; then, whilst the seeker remains in position, the remainder of the posterior wall and the upper boundary of the external meatus, from the level of the seeker to the level of the roof of the tympanic antrum, can be cut away without fear of injury to any important structure. The dissection should be completed by the removal of the tympanic membrane and ossicles, and when this has been done a very complete view will be obtained of the medial walls of the tympanic cavity, the aditus,

and the tympanic antrum. Anteriorly, on the medial wall of the tympanic cavity, is the promontory, which marks the position of the first turn of the cochlea. Above and posterior to the promontory is the fenestra vestibuli. The fenestra cochleæ lies at the lower and posterior part of the promontory, in the anterior part of a recess called the fossula fenestræ cochleæ. Above the fenestra vestibuli is a ridge caused by the posterior horizontal part of the canalis facialis; this becomes continuous, on the medial wall of the aditus, with the vertical ridge which indicates the position of the vertical part of the canal. Above the latter is the horizontal ridge due to the lateral semicircular canal. The dissector should open the canalis facialis to expose the facial nerve; then he should open the lateral semicircular canal, and afterwards remove the bone above and posterior to it to expose the walls of the superior and posterior semicircular canals (Figs. 219, 220, 221).

Intrapetrous Part of the Facial Nerve and the Acoustic Nerve.

The facial and acoustic nerves have already been traced into the internal acoustic meatus (p. 112). The dissector should now open up the meatus and follow the facial nerve in its course through the petrous portion of the temporal bone. The canal which it occupies is termed the *canalis facialis* (O.T. *aqueduct of Fallopius*). It begins at the bottom of the internal acoustic meatus, and opens on the exterior of the skull at the stylo-mastoid foramen. Between its commencement and termination it pursues a curved course, and that, combined with the density of the bone, renders the dissection difficult.

Dissection.—On the side on which the middle ear has been opened from the lateral aspect and the canalis facialis has already been partially opened up, the dissector should complete the dissection of the intrapetrous part of the facial nerve and should examine the acoustic nerve.

Separate the temporal bone from the other cranial bones which still adhere to it, and fix it in the natural position (in a vice if possible). Remove the squamous portion by a horizontal saw cut at the level of the anterior surface of the petrous portion. Make a second horizontal saw cut, immediately above the roof of the internal acoustic meatus, and carry it laterally into the tympanum, in which it should emerge immediately above the already opened canalis facialis where the latter lies above the fenestra vestibuli. Then, with the bone forceps or chisel, remove the remains of the roof of the internal meatus and follow the facial nerve along the canalis facialis to the hiatus canalis facialis, and so expose the ganglion geniculi. Secure the

branches which arise from the ganglion and then follow the nerve backwards above the fenestra vestibuli. The greater part of the vertical portion of the canal has already been opened from the lateral aspect; the remainder can now be displayed by means of two saw cuts—(1) a frontal section (vertical transverse) carried medially from the lateral surface of the bone to the posterior border of the stylo-mastoid foramen; (2) a sagittal cut (vertical antero-posterior) carried from the posterior surface of the bone to meet cut (1). The portion of bone between the two cuts must then be removed, and the dissection must be completed with bone forceps. Three branches are given off from the facial nerve in the terminal part of the canal.

Intrapetrous Portion of the Facial Nerve.—As the facial nerve traverses the petrous bone, it may be looked upon as consisting of four parts, which differ from one another in the relations they present and in the direction which they take. They are:—

1. A part within the internal acoustic meatus.
2. A very short part which extends from the bottom of the internal acoustic meatus to the ganglion geniculi.
3. A part which occupies that portion of the canalis facialis which runs along the medial wall of the tympanic cavity.
4. A part which extends vertically downwards to the stylo-mastoid foramen.

First Part.—In the internal acoustic meatus, the facial nerve runs almost directly laterally, in company with the acoustic nerve. In that stage of its course it lies in relation to the upper and anterior part of the acoustic nerve, and its motor and sensory roots join. At the bottom of the internal acoustic meatus it enters the canalis facialis.

Second Part.—The second part of the facial nerve is very short. It runs laterally, with a slight inclination forwards between the vestibule and cochlea, and very soon ends in the swelling termed the *ganglion geniculi*.

Third Part.—At the ganglion geniculi, the facial nerve bends suddenly and proceeds backwards and slightly downwards, in that portion of the canal which runs along the upper part of the medial wall of the tympanic cavity, immediately above the fenestra vestibuli (O.T. ovalis).

The first three portions of the facial nerve are nearly horizontal, and pursue a somewhat V-shaped course. The apex of the V is directed forwards, and corresponds to the ganglion geniculi.

Fourth Part.—The fourth part is vertical, and passes down-

wards, posterior to the pyramid, to gain the stylo-mastoid foramen.

36. Nerve to digastric (post. belly).
37. Nerve to stylo-hyoid muscle.
38. Posterior auricular nerve.

The *branches* which spring from or join the facial nerve during its passage through the temporal bone are:—

1. The greater superficial petrosal nerve,
2. Communicating twig to the lesser superficial petrosal,
3. External superficial petrosal nerve,

} from ganglion geniculi.

4. Nerve to stapedius.
5. Chorda tympani.
6. Communicating twigs to the auricular branch of vagus.

The *greater superficial petrosal nerve* has been examined

already (p. 241). Its origin from the ganglion geniculi of the facial nerve can now be seen.

The *communicating branch* to the lesser superficial petrosal arises from the ganglion geniculi, and unites with the fibres of the tympanic nerve which issue from the tympanic plexus.

The *external petrosal nerve* is not always present. It joins the sympathetic plexus which accompanies the middle meningeal artery.

The *nerve to the stapedius muscle* arises from the facial as it passes downwards posterior to the pyramid. It enters the base of the pyramid and thus reaches the stapedius muscle.

The *communicating twigs to the auricular branch* of the vagus arise a short distance above the stylo-mastoid foramen.

Chorda Tympani.—The chorda tympani represents to a large extent the sensory fibres set free from the trunk of the facial nerve. It is the largest branch given off by the facial during its passage through the *canalis facialis.* It takes origin a short distance above the stylo-mastoid foramen, and arching upwards and forwards, in a narrow canal in the petrous portion of the temporal bone (the canaliculus chordæ tympani), it appears in the tympanum by passing through the tympanic aperture of the canaliculus chordæ, below the base of the pyramid, and close to the posterior margin of membrana tympani. The bony tunnel which it occupies can easily be opened up in a decalcified bone, but is somewhat difficult to expose in the hard bone. After entering the tympanum the chorda tympani runs forwards, upon the upper part of the membrana tympani, under cover of the mucous layer. It crosses the handle of the malleus on the medial aspect near its root. Finally, reaching the anterior end of the tympanic cavity it crosses the anterior process (O.T. gracilis) of the malleus, passes above the tensor tympani, and traverses the medial end of the petro-tympanic fissure, which conducts it to the exterior of the skull. From its exit to its junction with the lingual nerve the chorda tympani has already been traced (p. 182).

Nervus Acusticus.—In the internal acoustic meatus the acoustic nerve lies at a lower level than the facial, and at the bottom of the passage it splits into two parts, termed the *cochlear* and *vestibular divisions.* The two divisions again subdivide and supply the different parts of the labyrinth of the ear through the foramina of the lamina cribrosa (Fig. 209).

Internal Ear.

Dissection.—After the examination of the intrapetrous part of the facial nerve and the acoustic nerve is completed the dissector should display the labyrinth of the internal ear by means of two saw cuts—(1) an antero-posterior vertical cut, carried from the upper surface of the bone downwards to the floor of the tympanum, along the junction of its medial and posterior boundaries; (2) a horizontal cut. This cut should be commenced at the apex of the petrous part of the temporal bone and should be carried laterally till it joins the vertical cut, posteriorly, and enters the tympanic cavity, anteriorly, at the level of the mid-height of the promontory. When the upper part of the petrous portion of the temporal bone, separated by the two cuts, is removed, the vestibular and cochlear parts of the labyrinth and portions of the semicircular canals will be displayed. The dissector should demonstrate the positions and curves of the semicircular canals and the canalis facialis by passing bristles through them.

Auris Interna.—The internal ear or labyrinth consists of an intricate system of cavities in the petrous part of the temporal bone, called the *osseous labyrinth*, and a series of hollow membranous structures, connected with the filaments of the acoustic nerve, which lie in the osseous labyrinth and constitute the *membranous labyrinth.*

The *osseous labyrinth* is composed of a chamber termed the vestibule, posterior to which are placed the three semicircular canals, whilst anteriorly is the cochlea. All the cavities communicate with one another. The corresponding membranous parts do not completely occupy the osseous chambers, and the intervening space is filled with a fluid termed the *perilymph.* The *membranous labyrinth* also contains a fluid which receives the name of *endolymph.*

Vestibulum.—The vestibule is a small bony chamber of ovoid form, which possesses an antero-posterior diameter of about 4 mm. (*one-sixth of an inch*). It is situated between the medial wall of the tympanum and the bottom of the internal acoustic meatus.

Into the posterior part of the vestibule the three semicircular canals open by *five round apertures*; whilst in its lower and anterior part is the opening of the *scala vestibuli* of the cochlea.

On the *lateral wall* is the fenestra vestibuli, which is closed, in the recent state, by the delicate periosteal lining of the chamber and by the base of the stapes. When those parts are removed, the vestibule communicates directly with the

tympanum. In the anterior part of the *medial wall* of the vestibule there is a circular depression, termed the *recessus sphæricus*; it is bounded posteriorly by a vertical ridge, called the *crista vestibuli*. In the bottom of the recessus sphæricus are some minute holes through which pass filaments from the acoustic nerve. In the *roof* of the vestibule is another depression, named the *recessus ellipticus*. It is placed posterior to the crista vestibuli.

A small aperture in the posterior part of the medial wall also deserves mention. It is the mouth of the *aquæductus vestibuli*—a small canal which passes backwards to

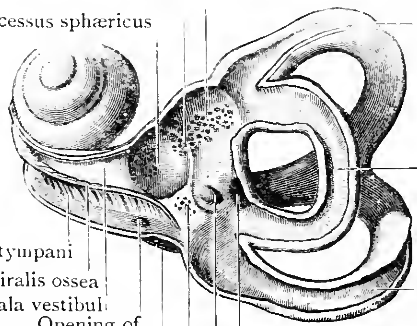

FIG. 223.—Interior of the Left Bony Labyrinth viewed from the lateral aspect. (Howden.)

the posterior surface of the petrous part of the temporal bone, where it opens under the dura mater.

Canales Semicirculares Ossei.—There are three bony semicircular canals or tubes placed posterior to the vestibule. They are bent upon themselves, so that each forms considerably more than half a circle, and they occupy planes at right angles to each other like three faces of a cube. They are termed superior, posterior, and lateral, and they open into the posterior part of the vestibule by five round orifices, the number of openings being reduced to five because the adjoining extremities of the superior and posterior canals are fused into a common canal called the *crus commune*, which opens by a single orifice. One extremity of each canal where it joins the vestibule becomes expanded into

what is termed its *ampulla*. There are, therefore, three ampullated ends.

The *superior semicircular canal* forms the highest part of the labyrinth. Its highest part lies beneath the eminentia arcuata on the anterior surface of the petrous part of the temporal bone. It is placed vertically, and is almost transverse to the long axis of the petrous part of the temporal bone. The *posterior semicircular canal*, which is the longest of the three tubes, is also vertical, and lies in a plane parallel to the posterior surface of the petrous part of the temporal bone. The *lateral semicircular canal* is the shortest of the

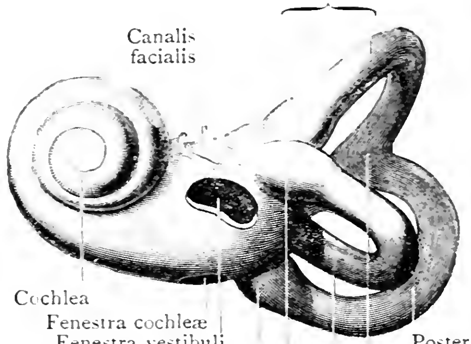

FIG. 224.—Left Bony Labyrinth viewed from lateral side. (Howden.)

tubes. It lies in a horizontal plane, in the angle between the superior and posterior canals.

Cochlea.—The cochlea is a tapering tube which is coiled spirally, for two turns and a half, around a central pillar, termed the *modiolus*. The appearance produced is somewhat similar to that of a spiral shell. The cochlea lies anterior to the vestibule; its base is directed towards the bottom of the internal acoustic meatus; its long axis runs antero-laterally from the base, and its apex lies in close relation with the canal for the tensor tympani muscle.

The cochlear tube rapidly diminishes in diameter as it is traced towards the apex of the cochlea. Its closed extremity is termed the *cupola*. The first turn which the cochlea takes around the modiolus produces the bulging on

the medial wall of the tympanum which has been described under the name of the promontory (Figs. 223, 209).

The *modiolus* is thick at the base, but rapidly tapers towards the apex. Its base abuts against the bottom of the internal acoustic meatus. It forms the inner wall of the cochlear tube, and winding spirally round it, like the thread of a screw, is a thin lamina of bone, termed the *lamina spiralis*, which partially subdivides the osseous tube into two passages.

Numerous minute canals traverse the modiolus, and one more conspicuous than the others, called the *longitudinal canal of the modiolus*, extends along its centre. The spiral lamina also is tunnelled by small canals in communication with those in the modiolus, whilst one, the *spiral canal of the modiolus*, winds spirally around the central pillar in the attached margin of the spiral lamina. All these channels convey filaments from the cochlear division of the acoustic nerve to the membranous cochlea, whilst the spiral canal lodges the *ganglion spirale cochleæ*, which is the peripheral ganglion of the cochlear part of the acoustic nerve.

The *membranous cochlear tube* or *ductus cochlearis* is placed between the free margin of the spiral lamina and the opposite side of the wall of the cochlear tube. It completes the subdivision of the bony cochlea into two compartments, which are termed the scala tympani and the scala vestibuli. The *scala tympani* is the larger of the two. It begins at the fenestra cochleæ, where the secondary membrane of the tympanum shuts it off from the tympanic cavity. At the apex of the cochlea it communicates with the scala vestibuli by means of an aperture termed the *helicotrema*. At the base of the cochlea the *scala vestibuli* communicates with the lower and anterior part of the vestibule. The perilymph therefore, in the semicircular canals and vestibule, is directly continuous with that in the scala vestibuli and scala tympani.

It can now be understood how vibrations of the membrana tympani are communicated to the perilymph within the osseous labyrinth. The chain of auditory ossicles, through the base of the stapes, affects the perilymph in the vestibule. The vibrations of the perilymph passing along the scala vestibuli into the scala tympani affect in turn the secondary membrane of the tympanum, which is stretched across the fenestra cochleæ. With every inward movement of the membrana tympani and of the base of the stapes, there is an outward movement of the membrane of the fenestra cochleæ, and *vice versa*. The vibrations of the perilymph affect the endolymph in the membranous labyrinth, and thus excite the terminations of the acoustic nerve.

Membranous Labyrinth. — In the vestibule there are two membranous sacs, termed the utricle and the saccule. The *utricle* occupies the recessus ellipticus on the upper wall of the vestibule, and lies above

and posterior to the saccule. Into it open the *membranous semicircular ducts* which lie in the bony semicircular canals.

Each semicircular duct corresponds in general form with the semicircular canal in which it lies, but it is of smaller diameter. Its convex margin is attached to the adjacent part of the wall of the bony canal.

The *saccule* is smaller, and occupies the recessus sphæricus on the anterior part of the medial wall of the vestibule. It communicates by means of a short narrow tube, termed the *canalis reuniens*, with the ductus cochlearis or membranous cochlear tube.

The saccule and the utricle are only indirectly brought into communication with one another; a slender tube termed the *ductus endolymphaticus*

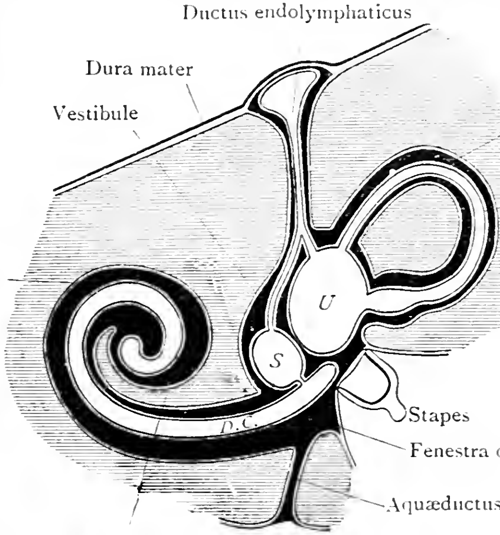

FIG. 225.—Diagram of the Osseous and Membranous Labyrinth. (Modified from Testut.)

U. Utricle. *S.* Saccule. *D.C.* Ductus cochlearis.

occupies the aquæductus vestibuli, and divides into two branches which pass respectively into the saccule and the utricle (Fig. 225).

The *ductus cochlearis*, or *scala media*, lies between the two scalæ of the bony cochlear tube. It ends blindly at each extremity, but close to its basal end it is brought into communication with the saccule by the *canalis reuniens*.

BULBUS OCULI.

THE bulbus oculi or eyeball is not perfectly spherical. Indeed, it may be said to be composed of the segments of two spheres. The anterior or corneal segment, which forms only about one-sixth of the entire eyeball, possesses a shorter radius than the posterior or scleral segment. The

anterior, clear corneal part of the eyeball appears, therefore, as a convex window or prominence on the front of the globe of the eye. The terms *anterior pole* and *posterior pole* are respectively applied to the central points of the anterior and posterior segments of the eyeball. The imaginary line which joins the two poles receives the name of the *sagittal axis*, whilst another line drawn in a frontal direction around the globe of the eye, midway between the two poles, so as to divide the eyeball into two hemispheres, is termed the *equator*. Imaginary *meridional lines* also are drawn between the two poles so as to cut the equatorial line at right angles.

Dissection of the Eyeball.—A satisfactory dissection of the globe of the eye can be made only when the eyeball is fresh, or after it has been hardened for several days in a 10% solution of formol. In the dissecting-room it is often impossible to obtain suitable specimens; but it is always easy to procure eyeballs of the pig, sheep, or ox, and those suit the purpose admirably. It is advisable, however, that the dissector should complete his study of the organ by the examination of a fresh human eyeball obtained from the *post-mortem* room. In point of size, and also in other particulars, the eyeball of the pig more closely resembles the human eyeball than the eyeball of the sheep or ox; but it is perhaps better that the student should begin with the eyeball of the ox, because the necessary dissection can be more easily carried out in it than in smaller eyeballs.

When the dissector has provided himself with six eyeballs obtained from oxen, he should remove from them the conjunctiva, fascia bulbi, ocular muscles, and fat, which adhere to them. Pinching up, with the forceps, the conjunctiva and the fascia bulbi close to the corneal margin, he should snip through those layers with the scissors and divide them round the whole edge of the cornea. He can then easily strip all the soft parts from the surface of the sclera, working steadily backwards towards the entrance of the optic nerve. A little posterior to the equator of the eyeball the *venæ vorticosæ* will be noticed issuing from the sclera, at wide intervals from each other; and as the posterior aspect of the eyeball is approached the posterior ciliary arteries and the ciliary nerves will be seen piercing the sclera around the entrance of the optic nerve.

Before the student begins the actual dissection of the eyeball, it is important that he should obtain a general conception of the parts which compose it. That can be done by sections made through three hardened specimens in three different planes. One specimen should be divided, at the equator, into an anterior and a posterior portion. Another should be divided, in an antero-posterior direction, into a medial and a lateral half. A third should be divided horizontally and a portion of the vitreous body should be removed (Fig. 226). When the sections are made, they should be placed under water in a cork-lined tray, and preserved for reference as the study of the eyeball is proceeded with.

General Structure of the Eyeball.—The eyeball consists of three concentrically arranged coats enclosing a cavity in which three refracting media are placed.

The coats or tunics are: (1) an external fibrous envelope composed of a posterior, opaque part, called the *sclera*, and an anterior, clear transparent portion, called the *cornea*; (2) a middle vascular envelope, known as the *uveal tract*, in which three subdivisions are recognised, viz., a posterior part called the *chorioid*, an anterior portion termed the *iris*, which

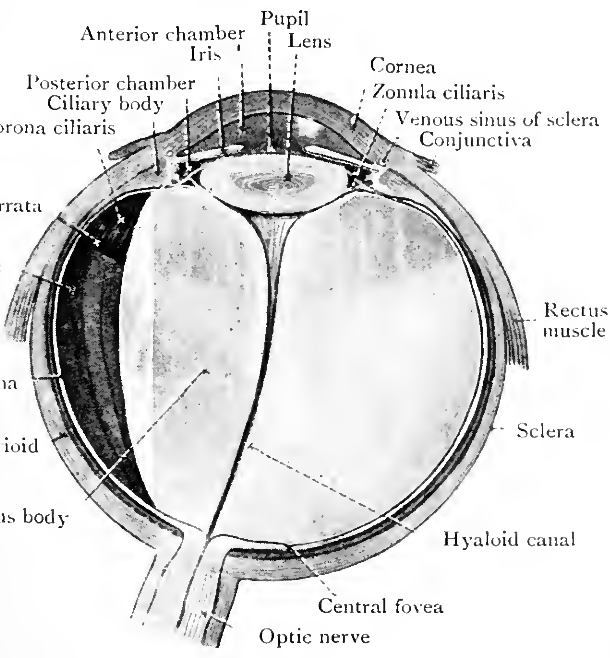

FIG. 226.—Diagrammatic section of Eyeball.

lies posterior to the cornea, and an intervening *ciliary body*; (3) the nervous internal tunic or *retina*, in which the fibres of the optic nerve are outspread.

The refracting media are: (1) the cornea; (2) posterior to the cornea a watery fluid called the *aqueous humour*, contained in a space partially subdivided by the iris into the *anterior* and *posterior chambers of the eye*; (3) the *crystalline lens*, behind the posterior chamber; and (4) the *vitreous body*, which occupies the posterior part of the interior of the eyeball.

Dissection.—**The superficial surface of the sclera and of the cornea should now be examined; but to complete the study of**

the external tunic a further dissection is required. Select an eyeball for that purpose, and make an incision, with a sharp knife, through the sclera at the equator. The incision must be made carefully, and the moment that the subjacent black chorioid coat appears the knife should be laid aside. The cut edge of the sclera should now be seized with the forceps, and the incision carried completely round the eyeball, with the scissors, along the line of the equator. The outer fibrous tunic is thus divided into an anterior and a posterior portion. Both parts must now be raised from the subjacent structures. As the anterior portion is turned forwards, some resistance will be met with, close to the margin of the cornea ; it is due to the attachment of the ciliary muscle to the deep surface of the sclera. The attachment can easily be broken through with the blunt point of the closed forceps ; as soon as that is done the aqueous humour escapes. In the case of the posterior part of the sclera, the complete separation of the sclera can be effected by dividing the fibres of the optic nerve close to the point where they enter the sclera from the inner side.

When the above dissection is successfully carried out, the outer fibrous tunic is isolated in two portions, whilst a continuous view of the intermediate vascular coat is obtained. The eyeball, denuded of its external tunic, should now be placed in a shallow vessel filled with water.

Sclera.—The sclera is what is commonly known as the white of the eye. It is a dense, resistant tunic, opaque-white in colour, which envelops the posterior five-sixths of the globe of the eye. It is thickest posteriorly, and becomes thinner as it is traced forwards. Near the cornea, however, it again becomes thicker, owing to the accession of fibres which it receives from the tendons of the ocular muscles. Except at the entrance of the optic nerve and close to the margin of the cornea, where it adheres to the surface of the subjacent ciliary muscle, the deep surface of the sclera is very loosely attached to the chorioid coat. Some pigmented flocculent connective tissue, called the *lamina fusca*, connects the two coats and traverses what is, in reality, an extensive lymph space, termed the *perichorioidal space.*

The point at which the optic nerve pierces the sclera does not correspond with the posterior pole of the eyeball. The *optic entrance*, as it is termed, is situated about 3 mm. to the medial or nasal side of the posterior pole and 1 mm. below it. There the outer fibrous sheath of the optic nerve, which is derived from the dura mater, blends with the sclera, and the bundles of nerve fibres pass through a number of small apertures. The perforated portion of the sclera through which the fibres of the optic nerve pass is called the *lamina cribrosa.*

The sclera is pierced also by numerous blood-vessels and nerves. The long and short posterior ciliary arteries, with the ciliary nerves, perforate the sclera around the optic entrance; four or five venæ vorticosæ issue from the interior of the eyeball by piercing the sclera a short distance posterior to the equator, at wide intervals from each other; whilst the anterior ciliary arteries pierce it near the corneal margin.

Anteriorly, the sclera is not only contiguous to, but is directly and structurally continuous with, the cornea. The region of union is termed the *corneo-scleral junction*, and the faint groove on the surface, which corresponds with it, receives the name of the *scleral sulcus*. At the junction the

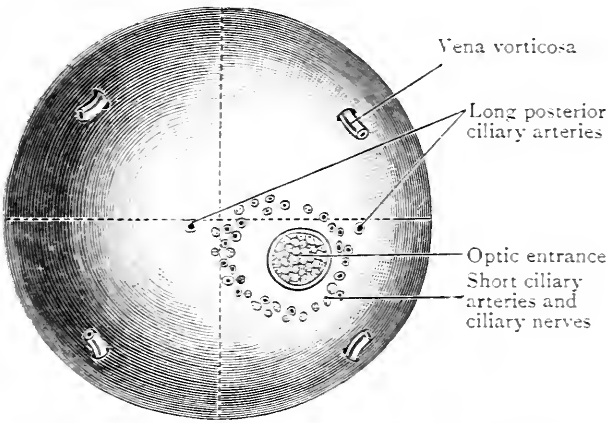

FIG. 227.—Diagram of the posterior aspect of the Left Eyeball. The excentric position of the optic entrance is somewhat exaggerated. (After Testut, modified.)

scleral tissue slightly overlaps the corneal tissue; therefore the line of union, when seen in section, is oblique. Close to the corneo-scleral junction, a minute canal in the substance of the sclera, termed the *sinus venosus scleræ* (O.T. canal of Schlemm), encircles the margin of the cornea.

Cornea.—The cornea forms the anterior sixth of the outer tunic of the eye. It is transparent and glass-like, and it forms the window through which the rays of light gain admittance into the eyeball. The curvature of the cornea is more accentuated than that of the sclera, and thus it constitutes the segment of a smaller sphere. When viewed from the posterior aspect it appears circular, but when looked at from the front it is seen to be slightly wider in the transverse

direction than in the vertical. That is due to the fact that the sclera overlaps it to a greater extent above and below than it does at the sides. The posterior, concave surface of the cornea forms the anterior boundary of the anterior chamber of the eyeball, and is separated by the aqueous humour from the anterior surface of the iris.

The anterior convex surface of the cornea is clothed with the conjunctiva, reduced to a transparent epithelial layer. On its posterior aspect there is an elastic, glassy stratum, termed the *posterior elastic lamina.* When the cornea is relaxed that membrane becomes wrinkled, and it can be torn away in shreds from the proper corneal tissue.

Ligamentum Pectinatum Iridis.—At the margin of the cornea the posterior elastic lamina is fibrillar, and some of its fibres are continued into the iris, forming the *ligamentum pectinatum iridis*, whilst others are prolonged backwards into the chorioid and the sclera. The ligamentum pectinatum iridis bridges across the angle between the cornea and the iris, and the bundles of fibres into which the posterior elastic lamina breaks up in that region constitute the boundaries of an annular mesh-work or sponge-like series of minute spaces termed the *spatia anguli iridis* (O.T. *spaces of Fontana*). The spaces communicate with the anterior chamber of the eyeball, and are filled with aqueous humour.

Tunica Vasculosa Oculi.—The middle or vascular tunic, frequently spoken of as the uveal tract, is exposed, in its entire extent, in the eyeball from which the sclera and the cornea have been removed. It is separable into three parts—(1) a posterior portion, the chorioidea; (2) a middle part, the corpus ciliare; and (3) an anterior segment, the iris.

Chorioidea.—The chorioid is the largest part of the vascular tunic. It lines the posterior segment of the eyeball, between the sclera externally and the retina internally. It is thickest posteriorly, where it is pierced by the optic nerve, and becomes thinner anteriorly, as it approaches its union with the ciliary body. Its superficial surface is connected with the deep surface of the sclera by some lax connective tissue, called the *lamina fusca*, and also by blood-vessels and nerves which pass from the one into the other. The deep surface of the chorioid is moulded upon the retina and is covered with a layer of deeply-pigmented cells which usually

adheres to the chorioid when that tunic is removed, although, in reality, it is a portion of the retina.

In the eyes of many mammals, but not in man, the posterior part of the chorioid, when viewed from the front, presents an extensive brightly-coloured area, which exhibits a metallic lustre. The appearance is due to the presence of an additional layer in the chorioid, termed the *tapetum*. In the horse, elephant, and ox, the tapetum is composed of fibres (tapetum fibrosum); in carnivora, it is formed of cells (tapetum cellulosum). In the ox, it is a brilliant green colour with a golden lustre; in the dog, it is white with a bluish border; in the horse, it is blue with a silvery lustre.

The chief bulk of the chorioid coat is composed of blood vessels. They are arranged in two well-marked layers, viz.,

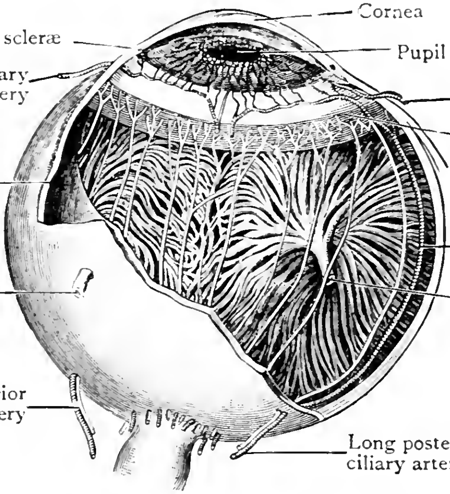

FIG. 228.—Dissection of the Eyeball showing the Vascular Tunic and the Arrangement of the Ciliary Nerves and Vessels.

a deep, closely-meshed capillary layer called the *lamina chorio-capillaris*, and a more superficial venous layer composed of the *vasa vorticosa*. The short posterior ciliary arteries pass forwards between the two vascular layers.

The eyeball in which the outer surface of the chorioid is exposed should be immersed in water and the pigment washed out of it by means of a camel-hair brush. The vasa vorticosa will then appear as white curved lines converging towards four or five points, from which the venæ vorticosæ take origin (Fig. 228).

Corpus Ciliare.—The ciliary body is separable into an antero-external part, the orbiculus ciliaris, and a postero-internal part, the corona ciliaris.

The *orbiculus ciliaris* consists of the ciliary muscle, the

ganglionated ciliary nerve plexus, and plexuses of arteries and veins associated with the iris and ciliary body. It is continuous with the iris internally, the sclera anteriorly, and the corona ciliaris and the chorioid posteriorly.

Musculus Ciliaris.—The ciliary muscle is composed of involuntary muscular tissue. The arrangement of its fibres can be seen only when thin sections of the eyeball are examined under the microscope. It is then obvious that the fibres are disposed in two groups, viz., a radiating and a circular.

The *radiating fibres* arise from the deep aspect of the sclera close to the margin of the cornea. From their origin they radiate backwards, in a meridional direction, and gain

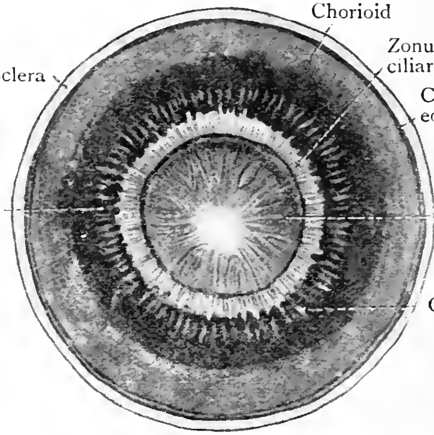

FIG. 229.—Posterior view of Lens and Zonula Ciliaris. (Professor Arthur Thomson.)

insertion into the chorioid coat in the region of the ciliary processes. The *circular fibres* consist of two or three bundles placed upon the deep aspect of the radiating portion of the muscle. They form a muscular ring around the outer circumference of the iris. The ciliary muscle is supplied by the oculo-motor nerve. It draws the anterior part of the chorioid forwards, and so relaxes the suspensory ligament of the lens, which then becomes more convex on account of its own elasticity.

***Dissection.*—To obtain a view of the ciliary processes, a frontal section should be made through an eyeball, a short distance anterior to the equator. The portion of the vitreous body which occupies the posterior segment of the eyeball should be carefully removed. When that is done, the deep aspect of**

the corona ciliaris will be seen. It is covered with ciliary processes which radiate backwards from the circumference of the crystalline lens. Wash out the pigment from the anterior part of the vascular tunic, in order to display the arrangement of the processes more fully.

A second dissection may be made, in another eyeball, with the object of exposing the ciliary processes from the front. In that case remove the cornea by cutting round the corneo-scleral junction with the scissors. The iris is then brought conspicuously into view, and may, with advantage, be studied at this stage. Several cuts in the meridional direction, and at equal intervals from each other, should, in the next place, be made

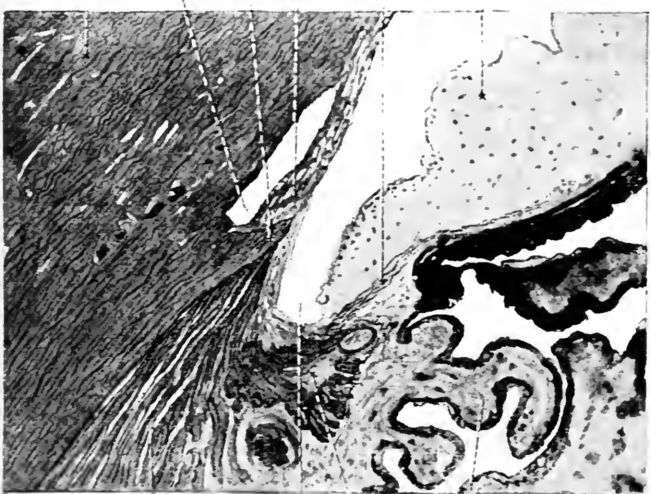

FIG. 302.—Section of Iridial Angle. (Prof. Arthur Thomson.)

through the anterior part of the sclera. The specimen should then be placed in a cork-lined tray, filled with water, and the strips of sclera should be separated from the ciliary muscle, bent aside and pinned to the cork. The last step in the dissection consists in the removal of the iris.

The *corona ciliaris* lies on the posterior aspect of the orbiculus ciliaris and is continuous, anteriorly, with the iris, and, posteriorly, with the chorioid. It consists of a number of larger folds, called the *processus ciliares*, 70 to 72 in number, which are intermingled with a number of smaller folds, called the *plicæ ciliares*. The ciliary processes extend from the anterior margin of the chorioid to the anterior margin of the

corona ciliaris, where they end in bulbous extremities. The bulbous ends occupy the space between the peripheral margin of the iris and the margin of the anterior surface of the crystalline lens, and they form the peripheral boundary of the posterior chamber of the eyeball. The *plicæ ciliares* are much less prominent than the ciliary processes. Both the processes and the folds are in relation, posteriorly, with the hyaloid membrane, which separates them from the vitreous body, and with the peripheral part of the zonula ciliaris (see p. 544) to which they are attached.

Iris.—The iris lies anterior to the crystalline lens, and it is separated from the cornea by the anterior chamber filled with aqueous humour. By its circumference it is continuous with the ciliary body, and it is connected, by the ligamentum pectinatum iridis, with the margin of the cornea.

The iris is circular in form, it is coloured differently in different subjects, and it has a central perforation termed the *pupil.* Its anterior surface is faintly striated in a radial direction. Its posterior surface is deeply pigmented. The pupil presents a very nearly circular outline,[1] and during life it constantly varies in its dimensions so as to control the amount of light which is admitted into the interior of the eyeball. The changes in the size of the pupil are produced by the two groups of involuntary muscular fibres which are present in the substance of the iris. One group is composed of muscular fibres arranged circularly around the pupil in the form of a *sphincter*; the second group consists of fibres which have a radial direction, and pass from the sphincter towards the circumference of the iris, so as to constitute a *dilatator muscle.* By some anatomists these radial fibres are considered to be *elastic* and not *muscular.* The circular fibres, which act as a sphincter, are supplied by the oculo-motor nerve. The dilator fibres are supplied by sympathetic nerve fibres.

Ciliary Nerves.—The ciliary nerves arise from the ciliary ganglion and the naso-ciliary nerve. They pierce the sclera around the optic entrance, and extend forwards, between the sclera and the chorioid, in the perichorioidal lymph space. They will be seen, in the specimen in which the sclera has

[1] It may be as well to mention here that the pupil in the ox and the sheep is greatly elongated in the transverse direction. In the pig, however, it is approximately circular.

been turned aside in separate flaps, in the form of delicate white filaments (Fig. 228). In the posterior part of the eyeball they occupy grooves on the deep surface of the sclera, and can be separated from it only with difficulty. Reaching the ciliary zone the ciliary nerves break into branches, which join in a plexiform manner and send twigs to the ciliary muscle, the iris, and the cornea. The long ciliary nerves are sensory nerves. The short ciliary nerves contain motor fibres derived from the motor-oculi, sensory fibres from the naso-ciliary nerve, and sympathetic fibres which convey motor impulses to the dilator muscle of the iris.

Ciliary Arteries.—There are three groups of ciliary arteries: (1) the short posterior ciliary arteries; (2) the long posterior ciliary arteries; and (3) the anterior ciliary arteries.

The *short posterior ciliary arteries*, branches of the ophthalmic, pierce the sclera around the optic entrance, and are distributed in the chorioid coat between the venæ vorticosæ and the lamina chorio-capillaris.

The *long posterior ciliary arteries*, also branches of the ophthalmic, are only two in number. They perforate the sclera, one on the medial side of the optic nerve and the other on its lateral side (Fig. 227), a short distance beyond the short ciliary arteries, and then pass forwards between the sclera and the chorioid. When they gain the ciliary zone each artery divides into an ascending and a descending branch, which anastomose with the anterior ciliary arteries at the periphery of the iris, and form an arterial ring termed the *circulus iridis major*. Branches are given off from the major circle to the ciliary muscle, the ciliary processes, and the iris.

The *circulus iridis minor* is the name applied to a second arterial ring in the iris at the outer border of the sphincter pupillæ.

The *anterior ciliary arteries* are very small twigs which arise from the branches of supply to the recti muscles. They pierce the sclera close to the margin of the cornea, take part in the formation of the circulus iridis major, and send twigs to the ciliary processes.

Venæ Vorticosæ.—From each venous vortex in the chorioid a large vein arises, which makes its exit from the eyeball by piercing the sclera, obliquely, a short distance posterior to the equator. They are four or five in number.

***Dissection.*—The vitreous body and retina, in the posterior part of the eyeball which was cut into two for the purpose of**

exposing the ciliary processes from the posterior aspect, should now be dislodged. By raising the chorioid coat from the deep surface of the sclera, under a flow of water from the tap, the dissector will bring into view the venæ vorticosæ as they enter the deep surface of the sclera. When the venæ vorticosæ are divided, and the separation of the two coats is carried backwards towards the optic entrance, the short posterior ciliary arteries, as they emerge from the sclera and enter the posterior part of the chorioid, will be seen.

To expose the external surface of the retina take the eyeball from which the sclera and cornea have been removed, and carefully strip off the iris, ciliary processes, and the chorioid, piecemeal, under water.

Retina.—The retina is composed of two strata—viz., a thin *pigmentary layer*, which adheres to the deep surface of the chorioid coat, and has been removed with it, and a delicate *nervous layer*, which is moulded on the surface of the vitreous body, but presents no attachment to it except at the optic entrance. The retina extends forwards, beyond the equator of the eyeball, and, a short distance from the ciliary zone, it appears to end in a well-defined, wavy or festooned border termed the *ora serrata*. This appearance, however, is somewhat deceptive. The nerve elements, it is true, come to an end along the ora serrata, but a lamina in continuity with the retina is in reality prolonged forwards as far as the margin of the pupil. The part in relation to the ciliary processes is exceedingly thin, and cannot be detected by the naked eye. It is termed the *pars ciliaris retinæ*. The portion on the deep surface of the iris is called the *stratum pigmenti iridis*.

During life the *retina proper* is transparent, but after death it soon assumes a dull greyish tint and becomes opaque. Posteriorly it is tied down at the optic entrance. When viewed from the anterior aspect the optic entrance appears as a conspicuous circular disc termed the *papilla nervi optici*, upon which is a depression, the *excavatio papillæ*. From that spot the optic nerve fibres radiate out so as to form the deep or anterior layer of the retina. The optic disc, in correspondence with the entrance of the optic nerve, lies to the medial or nasal side of the antero-posterior axis of the eyeball. Exactly in the centre of the human retina, and therefore in the axis of the globe of the eye, there is a small yellowish spot termed the *macula lutea*.[1] It is somewhat oval in

[1] There is no macula lutea in the eyeball of the ox or sheep.

outline, and a depression in its centre is called the *fovea centralis.*

Retinal Arteries and Veins.—In a fresh eyeball the *arteria centralis retinæ* will be seen entering the retina at the optic disc.[1] It immediately divides into a superior and an inferior division, and each of them breaks up into a large lateral or temporal division, and a smaller medial or nasal division. The various branches of the terminal divisions ramify in the retina as far as the ora serrata; but they do not anastomose with each other, nor with any of the other arteries in the eyeball.

The *retinal veins* converge upon the optic disc, and disappear into the substance of the optic nerve in the form of two small trunks which soon unite.

The retinal vessels, the optic disc, and the macula can all be examined in the living eye by means of the ophthalmoscope. The red reflex obtained from the fundus of the eyeball, so examined, is produced by the blood in the lamina chorio-capillaris.

Dissection.—For the study of the vitreous body and the crystalline lens, which together may be termed the "eye-kernel," it is better to take an eyeball which is not perfectly fresh (Anderson Stuart). The eyeball selected for this purpose should be allowed to stand untouched from one to three days, according to the season. Divide the coats of the eye round the equator; gently separate the cut edges, and turn the coats forwards and backwards, and the "eye-kernel" will slip out. It should be allowed to drop into a vessel filled with clean water. The examination of the parts forming the "eye-kernel" will be greatly facilitated if it is placed *en masse* in strong picro-carmine solution for a few minutes. When removed from the staining fluid, it should be well washed in water. In this way the hyaloid membrane enclosing the vitreous body, the capsule of the lens, and the zonula ciliaris, are stained red, and their connections become very apparent (Anderson Stuart).

Corpus Vitreum.—The vitreous body is a soft, yielding, transparent, jelly-like body, which occupies the posterior four-fifths of the interior of the eyeball. The retina is spread over its surface as far forwards as the ora serrata, but is in no way attached to it, except at the optic disc. Anterior to the ora serrata, the ciliary processes are applied to the vitreous body and indent its surface. More anteriorly, the vitreous body presents a deep concavity, called the *fossa*

[1] When the living retina is examined with the aid of the ophthalmoscope it is not the vessels which are seen but the blood circulating through them, for the walls of the vessels are transparent.

hyaloidea, for the reception of the posterior, convex surface of the crystalline lens.

The substance of the vitreous body is enclosed within a delicate transparent membrane, which completely envelops it, and receives the name of the *hyaloid membrane*. Extending forwards through the midst of the vitreous mass, from the region of the optic disc to the crystalline lens, is a minute canal, lined with a tube-like prolongation of the hyaloid membrane, and containing a watery fluid. The canal is termed the *hyaloid canal*; it represents the path taken by a branch of the arteria centralis retinæ, which, in the fœtus, extends to and supplies the capsule of the lens, but afterwards disappears.

The hyaloid canal, as a rule, cannot be seen in an ordinary dissection of the eyeball; but if the "eye-kernel" is shaken up in the picro-carmine solution as recommended by Anderson Stuart, it may sometimes be rendered evident through the staining fluid entering it. It is represented diagrammatically in Fig. 226.

Zonula Ciliaris (O.T. **Zonula of Zinn**).—Between the corona ciliaris externally and the margin of the lens internally lies a fibrous membrane called the zonula ciliaris. Its peripheral margin is attached to the posterior surfaces of the ciliary processes and the hyaloid membrane, and its central margin is connected with the lens. As it approaches the margin of the crystalline lens, it splits into two parts, viz., an exceedingly delicate, deep lamina, which lines the fossa hyaloidea, and a more superficial, stronger part, which becomes attached to the capsule of the crystalline lens.

The zonula ciliaris lies subjacent to the ciliary processes, and is radially wrinkled in correspondence with the depressions between the processes. Thus, the elevations or wrinkles of the zonula extend into the intervals between the ciliary processes, whilst the ciliary processes in their turn lie in the depressions between the wrinkles of the zonula. When the eye is fresh, these opposing parts are closely adherent.

The zonula ciliaris is strengthened by radially directed elastic fibres, and the anterior and stronger of the two layers into which it divides is called the *suspensory ligament of the lens*. It is attached, mainly, to the anterior surface of the capsule of the lens a short distance beyond the margin of that body, but this is not the only attachment of the suspensory ligament. Some of its fibres are attached to the circumference or equator of the lens (equatorial fibres), whilst others

are fixed to its posterior surface close to its margin (post-equatorial fibres).

In that way the crystalline lens is firmly held in its place in the fossa hyaloidea. Further, the degree of tension of its suspensory ligament is influenced by the radiating fibres of the ciliary muscle, which by their contraction pull upon the ciliary processes, and produce relaxation of the zonula ciliaris.

Spatia Zonularia (O.T. **Canal of Petit**).—In reality the spatia zonularia constitute a more or less continuous circular lymph space, which surrounds the circumference of the lens.

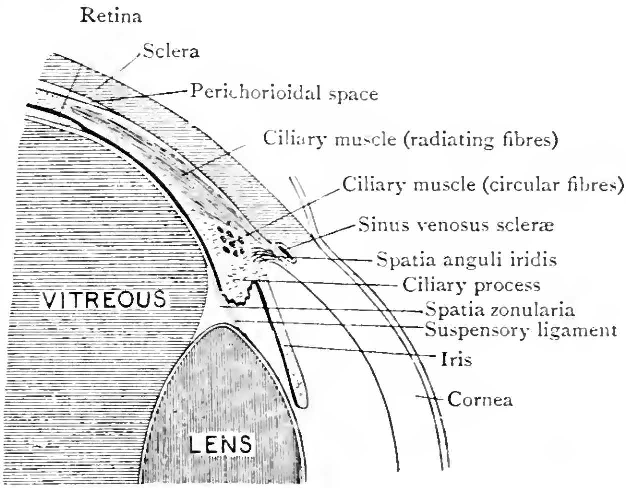

FIG. 231.—Diagrammatic representation of the Ciliary Region, as seen in vertical section.

It lies between the anterior and posterior layers of the suspensory ligament and is filled with a watery fluid.

If the point of a fine blow-pipe is introduced into the spatia zonularis through the suspensory ligament, the spatia can be partially, or, perhaps, completely, inflated with air. Then the spatia present, collectively, the appearance of a circular sacculated canal.

Dissection.—**Remove the crystalline lens by snipping through the suspensory ligament with scissors.**

Lens Crystallina.—The crystalline lens is a biconvex, solid, and transparent structure which lies between the iris and the vitreous body, in the posterior wall of the posterior and anterior chambers. It is enclosed within a glassy, elastic capsule, to which the different parts of the zonula ciliaris

are firmly cemented, and it presents for study an anterior surface, a posterior surface, and a circumference or equator.

The *anterior surface* is not so highly curved as the posterior surface. Its central part, which corresponds with the pupillary aperture of the iris, looks, through the pupil, into the anterior chamber of the eye. Around that part the margin of the pupillary orifice of the iris is in contact with the lens, whilst nearer the equator the anterior surface of the lens is separated from the iris by the fluid in the posterior chamber of the eyeball. The *posterior surface* of the lens presents a higher degree of curvature than the anterior surface, and is received into the fossa hyaloidea of the vitreous body. The *equator* or *circumference* is rounded. It forms one of the boundaries of the spatia zonularia. The manner in which the zonula ciliaris is attached to the capsule in this vicinity has been described already.

Faint radiating lines may be seen on both surfaces of the lens, and they give a clue to its structure. They indicate the planes along which the extremities of the lens-fibres come into apposition with each other.

The *capsule* of the lens is a resistant glassy membrane, which is considerably thicker anteriorly than posteriorly.

> ***Dissection.***—The anterior wall of the capsule may now be divided with a sharp knife. A little pressure will cause the body of the lens to escape through the opening. The stained capsule can be very advantageously studied whilst floating in water.
>
> If the lens body is compressed between the finger and thumb, it will be noted that the outer portion or *cortical part* is soft, whilst the central part or *nucleus* is distinctly firmer. When the lens is hardened in alcohol it can easily be proved that it is composed of numerous concentrically arranged laminæ.

Chambers of the Eyeball.—The *anterior chamber* of the eyeball is the space between the cornea, anteriorly, and the iris and central part of the lens, posteriorly. At the irido-corneal angle it is bounded by the ligamentum pectinatum iridis, and there the aqueous humour which fills this chamber finds access to the spatia anguli iridis.

The *posterior chamber* is a circular space or interval which is bounded, anteriorly, by the posterior surface of the iris, and, posteriorly, by the circumferential part of the anterior face of the lens. Peripherally, the posterior chamber is closed by the thick anterior projecting ends of the ciliary processes. It also is filled with aqueous humour.
